One day fever: temperature of 100.4 F. or over in only one 24 hour period after the first 24 hours.

Morbidity: temperature of 100.4 F. or over on any two consecutive days, not including the first 24 hours after delivery.

Intrapartum fever: temperature of 100.4 F. or over during labor.

It is evident that in neither case did the patient die of toxemia of pregnancy or because of the failure of the treatment for eclampsia, which was under complete control long before even the induction of labor was attempted. Such deaths may be prevented only by improvements in our methods of inducing labor and of delivery.

There were 129 babies (including nine sets of twins) born to the 120 mothers in this series. The incidence of twins was one set in 13.3 cases, almost five times the average incidence for all deliveries. This substantiates the belief that toxemia and eclampsia occur more frequently in multiple pregnancies than in single pregnancies. The records of four of the babies were mislaid, but of the remaining 125 thirty-six died, a gross mortality rate of 28.8 per cent. Antepartum eclampsia was fatal for the baby nearly twice as often (42.8 per cent) as was intrapartum (22.2 per cent) or postpartum (17.4 per cent) eclampsia.

The question of a control series of cases has often arisen, but the idea has always been abandoned. It obviously would be unfair to the patient with convulsions to deny her a treatment which is nearly 100 per cent effective (it actually was 100 per cent effective in this series, because in every one of the 120 cases, including the two patients who died, the acute eclampsia state was completely controlled). Further-

more, since somewhat similar methods of treatment have been reported from other clinics with less favorable results, we feel that the difference in results may be attributed to the incorporation of veratrum viride as a therapeutic agent in our system of treatment of eclampsia.

The actual details of treatment may be illustrated best, perhaps, by quoting the set of orders which might be written for a patient with eclampsia. These would read as follows:

1. Give 10 minims (0.6 cc.) of veratrum viride immediately; repeat every ten to fifteen minutes until the pulse rate is below 60 or the blood pressure is below 120 systolic; thereafter, until the patient is conscious, repeated in 3 to 10 minims (0.2 to 0.6 cc.) doses if the pulse rate goes over 80 or the blood pressure over 150 systolic; after the patient is conscious and cooperative, give 3 to 10 minim doses if the patient is nauseated or has severe headache, marked visual disturbances or epigastric pain or convulsions.
2. Give 10 cc. of 50 per cent magnesium sulfate by deep injection immediately, 5 cc. every six hours for four doses and then 5 cc. every twelve hours for four doses.
3. Give 500 cc. of 20 per cent dextrose intravenously at once; repeat every six to ten hours until consciousness returns.
4. Catheterize and give a soapsuds enema immediately.
5. Check the pulse and blood pressure hourly as long as coma persists, then every two to four hours while the patient is awake.
6. Force fluids (5,000 cc. daily) by mouth as soon as possible.
7. Give no sedatives except for extreme restlessness or labor.
8. Institute a diet free of salt as soon as tolerated.
9. Measure the fluid intake and the urinary output; examine the urine daily for albumin.

The usual precautions are observed during convulsions and coma. A mouth gag is kept available for protecting the tongue; postural drainage is used when saliva and mucus are excessive. No effort is made to isolate the patients; they are kept in the open thirty bed ward. Parenthetically it may be noted that the three commonest causes of restlessness in semicomatose patients are a full bladder, a full rectum and labor pains. A modified Gwathney technic is used during labor.

The effect of hypodermic injection of a therapeutic dose of veratrum viride is startling and may cause undue alarm to those unused to seeing it. The blood pressure falls rapidly, sometimes to as low as 50 systolic. This marked fall is transitory but is followed by a more or less prolonged period during which the pressure is well below the original level. The heart beat is slowed to 40 per minute in some cases but it soon picks up and remains at 60 to 80 until the effect of the drug has worn off. The pulse rate usually follows the blood pressure level fairly closely. Atropine or morphine sulfate or both are antidotes for veratrum viride; neither was needed in this series. Vomiting is an early effect. The vomitus is copious and usually green or black, possibly indicating excretion of toxic materials from the liver. The degree of vomiting varies with the individual susceptibility of the patient. The respiration is always slowed considerably but never to such a degree as to be harmful.

It should be emphasized that individual susceptibility to the drug is marked. For this reason the treatment cannot be absolutely standardized. The size and number of doses can be gaged only by the reaction of the patient.

COMMENT ON THE ACTION OF VERATRUM VIRIDE

If the initial premise—that abnormal vasoconstriction is a fundamental pathologicophysiological phenomenon in eclampsia—is correct, then elevated blood pressure

becomes a simple physical fact and the action of veratrum viride is easily explained. Our concept of the sequence of events (as outlined in the chart at the beginning of this article) is that the products of conception produce or cause to be produced some kind of vasoconstricting agent (a "toxin") and that hypertension develops through the action of the simple physical law that if pressure is made on the compressible walls of a closed system containing fluid the pressure of the contained fluid rises. If this is true, it is no longer necessary to invoke the theory that the hypertension is a protective phenomenon, a defensive mechanism or the response of the arteriolar tree to a demand on the part of the kidneys or the brain for more pressure. According to the last mentioned theory, increasing vasoconstriction and hypertension are beneficial in the presence of toxemia and eclampsia because they tend to maintain adequate circulation; according to our concept, increasing vasoconstriction (and its inevitable companion hypertension) is detrimental, followed as it is by anoxemia, retention of waste products, edema and even necrosis.

Veratrum viride is apparently a vasodilator (Solis-Cohen and Githens,² Hare,³ Cramer⁴) and in the presence of eclampsia acts by relieving widespread vasoconstriction. Dilation of the arteriolar bed with this drug causes a more normal blood supply to become available to the tissues, and various therapeutic agents (magnesium sulfate and dextrose, for instance) have more ready access to them. A drop in blood pressure follows relaxation of the contracted arterioles as surely as a rise in pressure follows arteriolar constriction. But we emphasize that veratrum viride is not used in cases of eclampsia for the express purpose of overcoming high blood pressure, although this secondary phenomenon may be beneficial when an overtaxed heart is about ready to fail or a weakened artery to burst. We consider that the primary function of veratrum viride in eclampsia is to induce generalized vasodilatation (vasorelaxation) with a consequent improvement in arterial circulation to all parts of the body.

Table 8 gives in detail the treatment followed in a fairly typical case of antepartum eclampsia.

SUMMARY

In a series of 120 consecutive cases of eclampsia the gross mortality rate was 1.67 per cent.

The low mortality rate is attributed to the employment of a method of treatment which stresses the use of veratrum viride (a vasodilator), dehydration with dextrose and magnesium sulfate solutions, an increased fluid intake and the withholding of sedation.

Recovery from the acute stage was the criterion for determining when induction of labor should be attempted, and the simplest methods of induction were tried first. In the forty-three cases of antepartum eclampsia requiring induction of labor the average interval between apparent control of convulsions and the first attempt to induce labor was almost fifty-eight hours.

In no case did the treatment fail, and there were no deaths from eclampsia or any of its immediate complications. The two deaths which did occur were from sepsis and occurred on the fourteenth and the sixty-fifth day respectively post partum.

ABSTRACT OF DISCUSSION

DR. HENRY LYNDE WOODWARD, Cincinnati: In the ten year period covered by this report, from 1940, we have delivered 19,989 mothers in our service at the Cincinnati General Hospital, with 120 eclamptic, an incidence of 0.6 of 1 per cent. Of the 120 with eclampsia, two died of sepsis, one two weeks and the other two months after the last convulsion, an uncorrected mortality of 1.67 per cent. I can add to this series, treated in the same way and during the same period, seven private consultations, with no deaths, increasing the total to 127 cases with two deaths, an uncorrected mortality of 1.57 per cent. These figures speak for themselves. The treatment outlined in the paper is just as valuable in preventing eclampsia in the severely toxic as it is in the treatment of the patient in convulsions. Without the use of a preparation of veratrum viride many more of these patients in this large group, which included many toxic patients, would have gone on to the convulsive stage. Many of the group of 120 patients with eclampsia were emergency cases, sent to the hospital only after the convulsions developed, and many of them had no antepartum care or had inadequate care. Most of our toxic patients are sent in early from the clinics or by their physicians, and in this group convulsions are rarely allowed to occur. The induction of labor is used very conservatively, not only for the patients with eclampsia but also for the severely preeclamptic patients. It is never attempted while the nervous symptoms which precede a convulsion are present, such as headache or epigastric pain. These symptoms can be immediately controlled by the hypodermic use of the preparation of veratrum viride. It is during the lull which follows the storm that such attempts at induction are made, and only by as conservative means as possible. The point that I wish to bring out most emphatically is that this treatment cannot be standardized but must be used in each individual case according to the results obtained. The best indicators are the slowing of the pulse and the drop in the blood pressure. Both of these indicate a desirable blood vessel relaxation and need cause no alarm. Both the magnesium sulfate by deep intramuscular injection and dextrose intravenously aid in the results, but the essential feature is the action of the veratrum viride bringing about vascular relaxation, with slowing of the pulse and a drop in blood pressure, thus preventing or controlling the convulsions.

DR. J. I. HOFBAUER, Cincinnati: In the treatment of eclampsia two cardinal aspects require consideration: sedation of the midbrain by magnesium sulfate, chloral, morphine or phenobarbital and relief of vasospasm. Repeated applications of ultraviolet rays, hypertonic dextrose solution and morphine proved, both clinically and experimentally, to effect vasodilatation and to counterbalance the vasospastic effect of post-pituitary on the coronary arteries. Recently I have been employing nicotinic acid and papaverine hydrochloride, with its marked vasodilating effect, as a useful adjunct. Nature apparently provides during normal pregnancy a powerful vasodilator mechanism by storing in the placenta remarkably large amounts of acetylcholine. The immediate contact of the placenta with the maternal circulation and the well known formation of syncytial buds, which through their disintegration carry into the blood stream specific placental elements, call for consideration in this respect. Augmented thyroid activity during pregnancy with increased quantities in the blood of thyroxine and iodine accounts for a heightened responsiveness of the arterioles to vasopressin. Certain split products of proteins and disturbance of salt balance of the blood also tend to make the blood vessels more sensitive to vasopressin. Acting on the supposition of an integrating mechanism concerned with maintaining during pregnancy normal calibers of the arterioles, I had recently the acetylcholine content of placentas obtained from six patients with pronounced preeclampsia determined. The comparatively low figures obtained in five instances seemed to point to a placental disorder, possibly correlated with the occurrence of placental infarcts and autolysis in the late toxemia of pregnancy. If verified and corroborated by further data, the new aspect of placental deficiency in storing acetylcholine, offered as it is with all due reserve, may help in clarifying the perplexity of the origin of eclampsia. If the view is acceptable that eclampsia actually represents the manifestation of height-

ened functional activity of the hypothalamus with outbursts of somatic and sympathetic activity through mediation of the hypophysis, an explanation would readily present itself for the increase of gonadotropic hormones in the blood, the seasonal variations and the occurrence of hemorrhagic lesions in the gastrointestinal tract in preeclampsia and eclampsia.

DR. RICHARD D. BRYANT, Cincinnati: Dr. Hofbauer has possibly thrown a little light on that place that we had marked in our chart as "toxin" in quotation marks, admitting that we didn't know what it is. His discussion is very interesting.

CANCER OF THE LARYNX

RELATION BETWEEN GROSS ANATOMY, MICROSCOPIC STRUCTURE AND RADIOSENSITIVITY

MAX CUTLER, M.D.

Director, Chicago Tumor Institute; Consultant, U. S. Veterans Facility, Hines, Ill.

CHICAGO

A marked difference of opinion exists as to the relationship between microscopic structure and radiosensitivity. This fact complicates the management of many forms of cancer, especially those in which a decision between surgery and irradiation has to be made. My purpose in this communication is to discuss the clinical and pathologic factors related to radiosensitivity of cancer of the larynx, with special emphasis on the value of biopsy in estimating the prognosis and guiding the treatment. This communication is based on a study of approximately 300 cases of cancer of the larynx observed during the last ten years.

Before the advent of irradiation in the treatment of cancer of the larynx, surgeons recognized a relation between their surgical results and the histologic structure of the lesions. This clinical experience and Broders' ¹ microscopic studies in the grading of cancer led to the view that in general the highly differentiated forms of carcinoma of the larynx (grades 1 and 2, Broders) yielded the best results, whereas the most undifferentiated forms (grades 3 and 4, Broders) yielded the worst results.²

With the advent and development of irradiation, the radiotherapists were soon impressed with the marked differences in radiosensitivity and radiocurability of different forms of cancer of the larynx, and numerous efforts have been made to correlate histologic structure with radiosensitivity and radiocurability. On the results of these studies there is considerable divergence of opinion, and since the microscopic appearances found at biopsy are used by many in deciding between the major procedures of laryngectomy and irradiation in certain cases, the practical importance of this problem is at once obvious.

The literature on this subject contains numerous general discussions but few comprehensive studies. The view that the histologic structure of the biopsy is of

practical value in helping to choose between surgery and irradiation in intrinsic cancer of the larynx is expressed by Gordon New and is based on the clinical and pathologic experience of New and Broders. A similar view is held by the Jacksons and is based on their experience in collaboration with the microscopic studies of Konzelmann.³

Other expressions on this subject may be summarized as follows: Lenz, Coakley and Stout ⁴ state that keratinized carcinomas of the larynx are radioresistant. Schinz and Zuppinger,⁵ however, have reported favorable results of irradiation in twenty-five cases of adult hornifying carcinoma of the larynx. Vogel⁶ states that the histologic differentiation between radiosensitive and radioresistant carcinomas is impossible. The view that the histologic structure is of minor importance and is of limited value in estimating radiosensitivity and determining the type of treatment in laryngeal cancer is shared by Adam,⁷ Kriegsmann,⁸ Quick,⁹ and Harris and Klemperer.¹⁰

DEFINITION OF RADIOSENSITIVITY

The most satisfactory definition of a radiosensitive tumor is that it is one which can be completely sterilized without permanent damage to the surrounding normal

Fig. 1 (case 1).—Carcinoma of the laryngeal vestibule indicating the tendency of these tumors to remain confined to the superior portion of the larynx. In this specimen the carcinoma has respected the ventricular cavity and vocal cord but has invaded the piriform fossa and has destroyed part of the epiglottis. (Courtesy of Dr. Otto Saphir.)

tissues. Since the property of radiosensitivity is a matter of degree and is so intimately related to the efficiency of the treatment, it is impossible to draw a fine line of division between "radiosensitive" and "radioresistant" tumors.

Owing to lack of space, this article has been abbreviated for publication in *THE JOURNAL*. The complete article appears in the author's reprints.

Read before the Section on Pathology and Physiology at the Ninety-First Annual Session of the American Medical Association, New York, May 13, 1940.

The administration and staff of the U. S. Veterans Facility, Hines, Ill., gave their cooperation to the author in this work and Dr. Henri Coutard collaborated with him in problems relating to roentgen therapy.

CLINICAL-PATHOLOGIC CLASSIFICATION¹¹

The classification presented here embodies the principle of histogenesis, which seems to be an important factor in both the surgical and the radiation treatment of the disease.

Fig. 2 (case 1).—Section showing undifferentiated epidermoid carcinoma (grade 3-4). Note attempts at pearl formation.

Because of the confusion that exists in the surgical, laryngoscopic and radiologic literature in the use of the terms extrinsic and intrinsic cancer of the larynx, and since the so-called extrinsic forms are actually pharyngeal tumors, it seems best to classify carcinoma of the larynx with reference to the site of the origin of the tumor and not with reference to its extension. According to this conception, therefore, cancer of the larynx may be divided into four types: (1) laryngeal vestibule

Fig. 3 (case 1).—Epidermis following telecurietherapy.

(epiglottis, false cord), (2) ventricular cavity, (3) vocal cord, (4) subglottic area.¹²

Carcinoma of the Laryngeal Vestibule.—This group includes two subvarieties: (1) carcinoma of the free border and laryngeal surface of the epiglottis and (2) carcinoma of the false

cord. The two varieties are discussed under the general term vestibular carcinoma, because they are almost always involved together.

1. Carcinoma of the free border and the laryngeal surface of the epiglottis generally produces a bulky ulcerated tumor which may grow to fill the entire laryngeal vestibule. The epiglottis itself may be partially destroyed. Anterior extension may result in tumefaction of the soft parts between the hyoid bone and the superior border of the thyroid cartilage. A second form of epiglottic carcinoma appears as a smooth rounded dome-like swelling of the laryngeal surface of the epiglottis projecting into the vestibule. Ulceration may not be visible until late. A third type of epiglottic carcinoma arises from the free border of the epiglottis and spreads anteriorly into the vallecula.

2. Carcinoma arising from the false cord tends to remain confined to the supraglottic region. Extension to the preepiglottic space is common. Extension to the true vocal cords results in intermittent hoarseness. This may be the first symptom that brings the patient in for examination. Dyspnea is the most common clinical symptom. Pain is generally absent in the early stages. Difficulty in swallowing arises when the tumor has extended posteriorly to the pyriform fossa.

Carcinoma of the laryngeal vestibule has a tendency to grow rapidly and extend widely both by direct invasion and by lymphatic spread. This form is generally composed of undifferentiated cells with a high degree of radiosensitivity and is best treated by external irradiation. In spite of its wide invasion

Fig. 4 (case 1).—Appearance of patient seven years after treatment.

and lymphatic spread, it is sometimes cured by external irradiation. Especially favorable is carcinoma arising from the epiglottis even though it may be associated with metastasis to the lymph nodes. By virtue of its location, histologic type and diffuse bilateral invasion, it is outside the domain of surgery.

CASE 1.¹³—G. E. (figs. 1, 2, 3 and 4), a man aged 58, had an extensive papillary ulcerated lesion of the epiglottis and left pyriform sinus. There were metastases to the lymph nodes in the left upper cervical area. Biopsy revealed an undifferentiated epidermoid carcinoma. Telecurietherapy was given from July 20 to Sept. 8, 1933. The patient has been well and free from disease for seven years.

This is an example of a very extensive cauliflower vestibular carcinoma involving the epiglottis and extending to the pyriform fossa with metastasis to the left cervical lymph nodes. The histologic structure (fig. 2) shows a completely undifferentiated epidermoid carcinoma (transitional cell type). The site of origin, clinical features and microscopic structure combine to form a classic example of a highly radiosensitive carcinoma of the laryngeal vestibule. The property of radiosensitivity may be predicted from this microscopic picture with reasonable accuracy.

Carcinoma Arising in the Ventricular Cavity.—These tumors grow silently within the ventricular cavity without producing symptoms or signs over long periods. A sudden attack of dysp-

11. Classification according to Cutler, Max, and Buschke, Franz: *Cancer. Its Diagnosis and Treatment*, Philadelphia, W. B. Saunders Company, 1938.

12. A discussion of subglottic carcinoma is omitted here because of lack of space.

13. This case was reported in 1934 (Cutler, Max: *The Problem of Radiosensitivity*, J. A. M. A. 103:1204 [Oct. 20] 1934).

nea may be the first indication of disease. Laryngeal examination may disclose only a smooth elevation of the ventricular band without ulceration. When the lesion projects into the laryngeal lumen, biopsy may be made from the papillary projections without difficulty; however, when the tumor does not project into the laryngeal lumen biopsy is exceedingly difficult and often gives repeatedly negative results. The cells are generally undifferentiated, with a tendency to widespread invasion.

CASE 2.—M. S. (figs. 5, 6, 7 and 8), a man aged 57, had swelling and tenderness of the skin and subcutaneous tissues overlying the thyroid and cricoid cartilages anteriorly in the midline. An ulcerated lesion of the right false cord extended downward to the subglottic region. There was diminished mobility of the right hemilarynx. Cervical adenopathy was not present. Extensive destruction of the thyroid cartilage was present with impending perforation through the skin anteriorly. Roentgen therapy was given from July 7 to July 30, 1938, resulting in complete disappearance of the lesion. The patient has been well and free from disease for two years. A biopsy revealed an undifferentiated epidermoid carcinoma.

This is a classic example of an undifferentiated epidermoid carcinoma originating in the ventricular cavity, extending to the preepiglott-

Figure 5

Figure 6

Fig. 5 (case 2).—Swelling over region of thyroid cartilage before treatment, indicating extension of ventricular carcinoma through thyroid cartilage.

Fig. 6 (case 2).—Appearance of patient in May 1940, two years after x-ray therapy.

tic space, destroying parts of the thyroid and cricoid cartilages and extending to the cutaneous and subcutaneous tissues of the anterior surface of the neck. The high degree of radiosensitivity of tumors of this type accounts for their response to adequate irradiation in spite of the fact that their great extent includes the destruction of cartilage. X-ray examination of the soft tissue of the larynx before and after treatment discloses remarkable repair of the cartilage.

Carcinoma of the True Vocal Cord.—This type composes the vast majority (from 80 to 90 per cent) of endolaryngeal tumors. The lesion begins in the midportion of the free border of the true cord and extends anteriorly. Further extension anteriorly occurs either in the form of a thin layer of carcinoma extending along the superior and free borders of the cord or by an ulcerated destructive invasion of the cord itself. Extension then occurs to the anterior commissure and across the midline to the opposite cord. Early hoarseness is the most prominent clinical symptom. The clinical course is slow. Immobility of the cord constitutes a most important diagnostic and prognostic sign.

CASE 3.—M. G. (figs. 9 and 12), a man aged 43, had an ulcerated lesion involving the anterior two thirds of the right true cord extending to the anterior commissure. Both cords were freely movable. A biopsy revealed an adult hornifying squamous carcinoma. Treatment consisted of telecurietherapy from April 30 to June 6, 1933, resulting in complete disappearance of the lesion.

Fig. 7 (case 2).—Epidermite in 1938 following x-ray therapy.

ance of the lesion. Fifteen months after the completion of the treatment superficial leukoplakia developed at the site of the previous tumor. This lesion remained unchanged for four years, after which slight thickening was suspected and a laryngofissure was performed. Evidence of carcinoma was not found. The patient was free from disease for seven years and two months after irradiation.¹⁴

CASE 4.—O. M. (fig. 10), a man aged 73, had an ulcerated lesion of the anterior two thirds of the right true cord extending onto and crossing the anterior commissure and involving the anterior third of the left true cord. Both cords were freely movable. There was no fixation of the arytenoids. A biopsy revealed a papillary squamous carcinoma. Telecurietherapy was

Fig. 8 (case 2).—Section showing undifferentiated epidermoid carcinoma (grade 3-4); radiosensitive in spite of pearl formation.

given from Feb. 21 to April 11, 1935, resulting in complete disappearance of the lesion. The patient has been well and free from disease for five years and four months.

CASE 5.—R. W. (fig. 11), a man aged 47, had an ulcerated lesion of the anterior three fourths of the right true cord extending forward to the anterior commissure and posteriorly to and

14. It is now obvious that the laryngofissure might have been avoided in this case.

CANCER OF THE LARYNX—CUTLER

1342

including the right arytenoid, with partial fixation of the right cord. The left cord was freely movable. There was some suggestion of subglottic extension. A biopsy revealed an adult hornifying squamous carcinoma with pearl formation. Roentgen therapy was given from July 2 to Aug. 26, 1936, resulting in complete disappearance of the lesion. The patient was well and free from disease for almost four years (June 1940).

Cases 3, 4 and 5 illustrate different stages of carcinoma of the true cord. In case 3 the lesion of the left cord had reached the anterior commissure (fig. 9). In case 4 it had crossed the anterior commissure and involved the opposite cord (fig. 10). The cords and arytenoids were freely movable in both cases and there was no clinical evidence of subglottic disease in either case. Both lesions were amenable to laryngofissure by Jackson's anterior commissure technic.

In case 5 the lesion had involved the entire right cord and anterior commissure and reached the right arytenoid, which was enlarged and slightly fixed (fig. 11). There was some evidence of subglottic extension. The extent of the disease, including involvement of the arytenoid, would have necessitated total laryngectomy.

The specimens taken for biopsy in all three cases showed adult hornifying squamous carcinoma, in spite of which the carcinoma disappeared completely under external irradiation and the patients have remained well and free from disease for seven

Under these circumstances it is impossible from clinical examination alone to know whether the lesion originated in the true cord or the false cord, yet this decision is most important because a fixed true cord lesion of this extent is generally incurable by irradiation and curable by laryngectomy, whereas a fixed lesion originating in the false cord is generally curable by irradiation and incurable by surgery. The surprising feature in this case is that in spite of the extent of the disease and apparent fixation of the hemilarynx the patient has been well and free from disease for almost six years. This result was first thought to be due to the more effective irradiation administered. This may be true; however, these studies raise the question whether the good results may not be explained by the site of origin in the false cord.

The accompanying table shows forty-five cases of cancer of the larynx in which treatment in twenty-five was by x-rays and in twenty by radium (telecurietherapy). Twenty-seven patients were well from one to two years and seventeen were well from three to seven years after treatment. The table is not presented as a statistical analysis of curability; a complete statistical study with ultimate results of treatment in the entire group of 300 carcinomas of the larynx is in preparation and will be published in the near future.

Fig. 9 (case 3).—Squamous carcinoma involving anterior three fourths of the left true cord, extending to the anterior commissure; cord freely movable.

Fig. 10 (case 4).—Squamous carcinoma involving the left true cord, extending across the anterior commissure, involving the right cord; both cords freely movable.

Fig. 11 (case 5).—Squamous carcinoma involving the right true cord, anterior commissure, right arytenoid and slight subglottic region with partial fixation.

years, six years and almost four years respectively. These three cases illustrate intrinsic carcinoma of the larynx treated by external irradiation for various reasons. Some patients whose lesions have been so extensive as to require laryngectomy have refused the radical operation. In some, the age or general condition contraindicated surgery. In still others irradiation was used as a therapeutic test and continued when the lesion proved to be radiosensitive.

There have been several cases of rather advanced carcinoma of the larynx involving both true and false cords with apparently complete fixation of the hemilarynx in which the lesion has disappeared completely following intensive external irradiation. It is interesting to analyze the possible reasons for this unexpected result. The following case is an example:

CASE 6.—W. M. (fig. 14), a man aged 58, had an extensive ulcerated lesion involving the entire left true and false cords. There were edema and fixation of the left arytenoid, definite subglottic extension and fixation of the left hemilarynx. Adenopathy was not present. Telecurietherapy was given from Sept. 24 to Nov. 12, 1934, resulting in complete disappearance of the lesion. The patient has been well and free from disease for five years and seven months.¹⁵

This is an example of an intrinsic carcinoma of the larynx involving the true and false cords with extension upward to the base of the epiglottis and downward to the subglottic region.

15. An independent carcinoma of the mucous membrane of the left cheek developed in November 1939; it was treated with telecurietherapy and has disappeared.

The forty-five cases included in this table were selected as representing radiosensitive and not necessarily radiocurable lesions. Attention is called to the following interesting features in the table: Twenty-two patients (50 per cent) had advanced lesions, inoperable technically and biologically. The histologic structure in group A is almost without exception the undifferentiated, transitional cell type (Broders' grades 3 and 4). The uniform relation between the site of origin (epiglottis, false cord and ventricle) and the microscopic features is striking.

Twenty-three patients with operable cancers of the larynx (group C) are well and free from disease (fifteen from one to two years and eight from three to seven years). Here is found a remarkably uniform relation between site of origin and histologic structure. In most cases biopsy revealed adult hornifying squamous carcinoma with pearl formation; in some it showed papillary plexiform epidermoid carcinoma.¹⁶ This group has a special significance in disproving the repeated statements in the literature that adult squamous carcinoma is radioresistant. The radiosensitivity in this group is accounted for by the fact that all the lesions

16. The absence of undifferentiated cellular elements distinguishes the histologic structure of this group from that found in group A, in which foci of adult features with pearl formation are often encountered.

were movable, indicating that true invasion of surrounding structures had not occurred. The radiocurability of many of the lesions is explained by their noninfiltrating character and the adequacy of the irradiation.

Fig. 12 (case 3).—Adult hornifying squamous carcinoma of the true cord (grades 1 and 2).

The six cases classified under "true and false cord, origin undetermined" (group B) present a uniform microscopic structure (fig. 14). It is best described as a papillary plexiform epidermoid carcinoma. All the lesions responded favorably in spite of their advanced stage and apparent fixation; consequently they are radiosensitive. It is my definite impression that lesions

Fig. 13.—Squamous carcinoma of the right true cord with subglottic extension and complete fixation; incurable by external irradiation.

of this histologic type are accompanied by a favorable prognosis. I suspect that their good prognosis is due to their papillary structure. It is not certain whether their origin is in the true cord or in the false cord, but it is probable that these lesions may arise in either cord. This group requires further study.

COMMENT

The microscopic structure of a biopsy specimen of cancer of the larynx is of some help in estimating the prognosis and in guiding treatment. Its value is, however, distinctly limited and unless the microscopic changes are interpreted in the light of the clinical and gross anatomic factors the biopsy alone may be highly misleading.

It is generally recognized that the specimen taken for biopsy may not be representative of the actual lesion. This error can be diminished by taking specimens for biopsy from different portions of the lesion. When biopsy discloses a highly undifferentiated carcinoma it may be assumed that the lesion is of this type. The contrary is not true.

The presence in epidermoid carcinoma of the larynx of adult differentiated morphologic features such as marked hornification and pearl formation in the absence of undifferentiated cellular elements does not, as is generally supposed, necessarily indicate radioresistance. It is fully established from this and other studies that when these microscopic features occur in a lesion which is papillary and movable and has not invaded the underlying structures it may be eradicated and cured by cor-

Fig. 14 (case 6).—Papillary plexiform epidermoid carcinoma; lesions of the structure generally radiosensitive.

rect external irradiation without permanent damage to the normal tissues.

If the biopsy shows a highly undifferentiated carcinoma, the radiosensitivity of the lesion may be predicted with reasonable certainty but its radiocurability is dependent on the extent of the disease, general condition of the patient, efficiency of the treatment and other factors of a biologic nature which are not understood.

If biopsy shows a highly undifferentiated carcinoma interspersed with differentiated elements in the form of foci of adult hornifying squamous areas and pearl formation, the latter are not significant (figs. 2 and 8). This is proved by the marked radiosensitivity and curability of a group of advanced lesions in which the biopsy showed these microscopic features.

There is some evidence to indicate that a papillary plexiform structure (fig. 14) is a favorable sign in the prognosis. Further observations are under way in an effort to determine this point.

The site of origin of a carcinoma of the larynx is one of the most important factors related to prognosis and treatment. Carcinoma arising in the false cords and epiglottis is generally undifferentiated and radiosensitive. Carcinoma arising in the true cord is generally differentiated, its radiosensitivity depending on the presence or absence of invasion.

Mobility of the lesion and the surrounding structures is a most important clinical sign. Complete mobility is highly favorable and with rare exceptions indicates radiosensitivity and under special conditions radiocurability. Fixation is usually due to neoplastic invasion, but it may be due to secondary infection and inflammation. Partial fixation frequently observed after biopsy is due to these factors and should be interpreted accordingly. Undifferentiated carcinomas usually remain movable in spite of their large size, and they may be recognized by this clinical fact, whereas a small infiltrating differentiated carcinoma may cause complete fixation of the cord when the lesion is quite limited in extent. The prognosis of the former is comparatively favorable under irradiation, in spite of its great extent and even of regional metastases, whereas the prognosis of the latter under irradiation is most unfavorable in spite of the fact that the lesion is very small and limited in extent. Conversely, the bulky undifferentiated carcinoma (grades 3 and 4) is totally unsuitable for surgery,

are more consistent and until more time has elapsed in order that the permanence of the irradiation cures may be more fully established. In the meantime, the newer technic can be utilized effectively in the treatment of inoperable laryngeal cancer and under circumstances in which operation is contraindicated or refused.

SUMMARY

The main result of this investigation is the demonstration that the radiosensitivity of cancer of the larynx cannot be determined on the basis of microscopic structure alone. The most important indication of radiosensitivity is mobility of the lesion and surrounding structures.

430 North Michigan Avenue.

ABSTRACT OF DISCUSSION

DR. CHEVALIER JACKSON JR., Philadelphia: I am essentially in agreement with Dr. Cutler's views as presented in this paper. It is our practice at Temple University Hospital to be guided first of all by the location of the lesion in the selection of treatment. We do consider the histologic aspect also. Biopsies are done in every case, and occasionally more than one biopsy. But it is in the borderline cases that we take into consideration the histologic features. For example, it is our present practice still to do laryngofissure when there are cordal lesions not reaching the posterior end of the cord and not fixed or markedly impaired in motion. In a series of ninety cordal cases reviewed recently there were fifteen of grade 1, thirty-nine of grade 2, sixteen of grade 3 and seven of grade 4. Yet in all those cases laryngofissure was done. I mention these figures just to show that we do not feel that a so-called high grade or undifferentiated tumor is necessarily a contraindication to surgery. Conversely, we do not believe either that the well differentiated tumor, the so-called radioresistant tumor, is one in which irradiation may not obtain excellent results. We are inclined to believe that the best prognosis in cancer of the larynx, regardless of the method of treatment, is probably obtained in the better differentiated tumors. In the so-called radiosensitive tumors, we have had the same experience as Dr. Cutler. They are not necessarily the more radiocurable ones. In one series of eighteen cases in which five years has elapsed, there were twelve intrinsic and six extrinsic cases; of the intrinsic cases, seven have been free from the disease five years or longer, and of the six extrinsic cases only one is known to be free from the disease. In this series the grading is of particular interest. Of the grade 1 cases in this series of eighteen two are among those showing no evidence of disease at the present time. Of the grade 2 cases, three show no evidence of disease. In the grade 3 cases there are no survivals. Of the grade 4 cases there are two which show no evidence of disease at the present time, one of those being a ventricular band lesion and the other a lesion of the aryepiglottic fold. Perhaps both of these would be considered vestibular, according to Dr. Cutler's classification. Dr. Cutler asked me to express an opinion on the slide that he showed representing a lesion involving the entire length of the cord. In that case we would consider laryngofissure entirely contraindicated, since there is impairment of motion. We would do a laryngectomy, I believe, if the patient was willing and there were no contraindications.

DR. FRANK W. KONZELMANN, Philadelphia: I endorse everything that Dr. Cutler has said. I am glad that he has emphasized the importance of distinguishing between radiosensitivity and radiocurability. Edward Chamberlain, at Temple, has taught us the importance of distinguishing those two conditions and that one doesn't necessarily follow the other. I believe with Dr. Cutler too, and it has been our experience in about 500 cases, that grading should not be the sole guide to treatment and prognosis. The extent of the lesion and the fixation of tissues are just as important. We grade all our tumors as a matter of record, but we try not to place too much importance on the degree of differentiation or the lack of differentiation. I should like to ask Dr. Cutler why he called the first slide he

*Forty-Five Patients with Cancer of the Larynx Treated by External Irradiation Well and Free from Disease, from One to Seven Years, Showing Relation Between Site of Origin, Histologic Structure and Radiosensitivity**

Clinical Type	Stage of Disease	Histologic Structure	Number Years Free from Disease							Total Cases
			1	2	3	4	5	6	7

Total			10	17	6	4	1	3	4	45

* Two patients not included in this table had subglottic recurrences in spite of adequate irradiation for lesions of the true cord, with apparently complete mobility. These cases will be included in the table of curability in a forthcoming statistical analysis of the entire group of laryngeal cancers.

† (a) Anterior two thirds of cord involved, anterior commissure free. (b) Anterior commissure involved with or without involvement of opposite cord. (c) Whole cord involved, lesion extending to anterior commissure and arytenoid. (d) Involvement of one or both cords with subglottic extension.

and the small invasive carcinoma (grades 1 and 2) is frequently curable by surgery.

The decision between surgery and irradiation in the borderline group of laryngeal cancers is frequently difficult and a matter of clinical judgment aided by the microscopic examination. The most important clinical factors are the site of origin and the extent of disease. With increasing experience, the indications and limitations of surgery and irradiation become more clearly defined and the borderline group diminishes.

The substitution of irradiation for surgery in strictly operable cancer of the larynx entails serious responsibilities. A radiation failure often precludes a surgical cure. The careful exploration of new radiation methods in specially organized clinics under controlled conditions is the only safe method of advancing our knowledge and, in fact, is leading to encouraging progress. The general application of these newly developed methods, however, must be postponed until the results

showed a papillary carcinoma. I have been much interested in the papillomas of the larynx, especially those that occur in the older individuals. Many times they have shown such a degree of lack of differentiation that we have been tempted to call them carcinoma, but none of these have shown any infiltrative tendencies. The first lantern slide was somewhat of an example of that type of case. I saw in the slide no evidence of invasion. We are tempted sometimes to be guided by changes in the epithelium above the basement membrane. In the case of papilloma I do not believe we have found a single case that has changed into the malignant type of lesion. Most of them respond well to superficial removal of the papillary growth without either irradiation or further extensive surgery. That carcinomas do occur and have a papillary tendency is beyond question, and we have called those, as Dr. Cutler's second slide represented, papillary carcinoma.

DR. MAX CUTLER, Chicago: I thank Dr. Jackson and Dr. Konzelmann for their courtesy in coming to discuss my paper. The photomicrograph to which Dr. Konzelmann refers was perhaps not clear but the biopsy showed definite papillary carcinoma on microscopic examination and the clinical picture was clearly that of a malignant lesion. Every effort should be made to correct the fallacy in the literature that highly differentiated adult squamous carcinoma with hornification and pearl formation necessarily indicates that the lesion is radioresistant. Such reports by pathologists often form the basis of decisions on major clinical procedures which are entirely erroneous.

CHEMOTHERAPY IN NONSPECIFIC INFECTIONS OF THE URINARY TRACT

PRESENT STATUS

EDWIN P. ALYEA, M.D.
AND
LOUIS C. ROBERTS, M.D.
DURHAM, N. C.

During the last ten years there has been remarkable advancement in diagnostic and operative procedures in urology. Revolutionary changes in the treatment of infections of the urinary tract now command our attention. Ten years ago the urologist was content to treat these infections expectantly or by administering drugs now believed to be of questionable efficacy. Intravenous neoarsphenamine in the treatment of coccic infection was perhaps the only specific drug therapy. In 1932 the ketogenic diet with the discovery of the bactericidal action of oxybutyric acid was the first step toward specific therapy in bacillus infections. However, many patients could not tolerate this unappetizing, nauseating diet. The following year specific bacteriophage was tried, but this met with very little success. In 1936 the first specific drug therapy, mandelic acid, was instituted in the treatment of infections of the urinary tract. It is bactericidal for most infections with *Streptococcus faecalis* and from 75 to 80 per cent of colon bacillus infections. *Staphylococcus*, *streptococcus* and *proteus* infections are rarely affected. In 1935 Temming, Klein, Pernice and their associates in Germany suggested azosulfamide (introduced as "prontosil") for colon bacillus infections. Two years later in this country

Helmholz,¹ Osterberg, Buchtel and Cook,² Herrold³ and in England Kenny⁴ showed in vitro the bactericidal power of urine after the administration of sulfanilamide and also the effect of the clinical application of sulfanilamide in infections of the urinary tract. This drug was particularly effective in colon, *proteus*, *streptococci* and *gonococci* infections and of little use in *Streptococcus faecalis* and *staphylococci* infections. Now for the first time there are available specific drugs, sulfanilamide, sulfanilyl sulfanilamide, sulfapyridine, sulfathiazole and mandelic acid for specific treatment of bacterial infections in the urinary tract.

ACTION

In spite of many theories on the action of the sulfonamide drugs they still remain a mystery. McIntosh and Whitby⁵ suggest that they may act directly as a bactericide or by preventing the invasive or multiplying power of bacteria. They may stimulate the nonspecific or specific body defenses or neutralize the toxic bacterial products. The quality or quantity of specific immune bodies, however, is not affected. There is no increase in phagocytosis, and the presence of peptone inhibits their action. They feel that the drug does not act as a simple germicide but more likely neutralizes some metabolic function or enzymatic activity that blocks the vital food supply of the bacteria. Others believe that it acts directly on the organism and that phagocytosis does play a part. Lockwood⁶ says that in the presence of traumatized or necrotic tissue sulfanilamide fails to sterilize a localized infection; it may alter the total metabolism of the organism or interfere with some specific function such as the capacity to digest protein. Long⁷ suggests that in infections of the urinary tract it may decrease the multiplication of bacteria and thereby diminish the production of toxins. There is also a definite sterilizing effect on the urine. We believe that in infections of the urinary tract the tissue reaction plays a greater part than direct bactericidal action.

PHARMACOLOGY

In man we⁸ have shown that after administration the sulfonamides are excreted in the urine with variations attributable to their different solubilities, and the excretion curves parallel the blood concentration curves (chart 1). This is not true, however, when renal function is diminished; here the blood concentration is higher and the excretion lower (chart 2). We⁸ have shown also that a standardization of dosage according to the phenolsulfonphthalein excreted in the first half hour gives a constant blood level even when there is a wide variation in renal function. In unilateral kidney disease it is evident (chart 3) that the excretion of the drug is exactly proportional to the excretion of phenolsulfonphthalein. In this particular case the good kidney with a normal phenolsulfonphthalein curve excreted 852 mg. in seven hours and the poor kidney

with a very low phenolsulfonphthalein curve only 43 mg., exactly comparable to the excretion of phenolsulfonphthalein. This fact, which was found true also for sulfanilyl sulfanilamide and sulfapyridine, should be kept in mind when one considers the concentration obtainable from kidneys badly damaged by infection. We⁸ have also shown that clinically the fluid intake does not affect the blood concentration or the actual amount of the drug excreted but does, of course, markedly affect the drug concentration in the urine. The differential excretion curves, therefore, of all the sulfonamide drugs follow their corresponding phenolsulfonphthalein curves, so that the total excretion depends on the drug used, the dosage administered and the renal function.

CHEMISTRY

Sulfanilamide, sulfanilyl sulfanilamide, sulfapyridine and, to a less extent, sulfathiazole form an inactive acetyl derivative in the body which is excreted in the urine along with the free or the active form. The blockage of renal tubules and ureters with acetyl sulfapyridine or sulfathiazole crystals when the patient has

Chart 1.—Comparison of sulfanilamide and sulfanilyl sulfanilamide in regard to blood concentration and excretion; normal phenolsulfonphthalein single dose was 3 Gm.

been on large doses is well known. Hill⁹ reports that there is a greater antibacterial action in the urine of a patient to whom sulfathiazole has been administered than there is in normal urine to which an equal amount of the drug has been added. White¹⁰ comments that perhaps sulfathiazole undergoes a decomposition in the body with the excretion of another stronger bactericidal cleavage product such as aminothiazole or a derivative of it.

BACTERIOLOGY IN VITRO

Studies in vitro by Helmholz¹¹ and Long and Bliss⁷ show that sulfanilamide has bactericidal power in both

acid and alkaline urine and that the higher the concentration the greater the number of organisms and the number of strains killed. Long and Bliss found that a concentration in vitro of 200 mg. per hundred cubic centimeters was necessary to render the urine bactericidal against the colon bacillus and that one of 50 mg. per hundred cubic centimeters was necessary against a staphylococcus and group D beta hemolytic streptococcus infection. There is a definite bacteriostatic level of the drug necessary for each kind of bacterium. Helmholz and his associates have suggested that sulfanilamide is more effective with alkalization of the urine, while Kenny,⁴ Melton¹² and others have shown that it is as bactericidal with a pH of from 5.2 to 6.8. Vest and his associates¹³ have shown that the bactericidal effect is not demonstrable with huge numbers of organisms; bactericidal action varies according to the concentration of the drug, the numbers of organisms present in the culture and the specific bacterium involved. Mellon and Shinn¹⁴ state that urine has a potentiating influence on the bacteriostatic effect of sulfanilamide on *Escherichia coli*. White¹⁵ shows that there is a definite relationship between the temperature and the streptococidal activity of the sulfonamide drugs; there was a marked increase in the bactericidal power between 37 and 39 C. He suggests that it is due to the effect of the temperature on the metabolic processes of the bacteria. This is substantiated clinically by Ballenger.¹⁶ Bliss and Long¹⁷ in comparing sulfanilamide and sulfapyridine found the latter in broth cultures a more effective bacteriostatic agent against *Bacillus typhi*, colon bacilli and group B of the beta hemolytic streptococcus and neither of them bactericidal for *Staphylococcus aureus*. The thiazole derivatives of sulfanilamide in the form of sulfathiazole and sulfamethylthiazole have been reported by Barlow, Helmholz,¹⁸ Herrell¹⁹ and Long²⁰ as being more effective against the staphylococcus than sulfapyridine or sulfanilamide. Sulfathiazole has a bacteriostatic effect on all bacteria in the urine. It differs from sulfanilamide and sulfapyridine in killing *Streptococcus faecalis* and staphylococcus with a lower concentration than is needed to killed gram-negative bacilli. *Pseudomonas* was the most resistant of all, requiring a concentration of 100 mg. per hundred cubic centimeters. Hill⁹ found that at a concentration of from 50 to 100 mg. per hundred cubic centimeters none of the sulfonamide drugs were bactericidal against large numbers of bacteria, but all were against small inoculums.

BACTERIOLOGY IN VIVO

Bacteriologic studies in vitro are, of course, most important in guiding the clinical application of these new drugs. However, conclusions drawn from the experimental work in vitro are not necessarily entirely

comparable *in vivo*. Particularly is this true in the treatment of infections of the urinary tract, since we have both the bactericidal action of the drug in the urine and the tissue or body reaction of the individual. The urologist has necessarily become a bacteriologist. The

Chart 2.—Comparison of absorption and excretion in patients with normal and poor renal function.

specificity of these various drugs for certain bacteria and indeed for particular strains of the same bacterium is quite evident. It is essential to know with what particular bacterium one is dealing if one is going to treat these patients intelligently. It has been found *in vivo* as well as *in vitro* that sulfanilamide is bactericidal for hemolytic streptococci, most of the strains of colon bacilli and proteus bacilli but for only a few strains of staphylococci and *Streptococcus faecalis*. Sulfathiazole in contrast has a higher therapeutic index against staphylococci. Kenny⁴ reported forty-six cases of acute colon bacillus infections of the urinary tract in which

TABLE 1.—Sulfanilamide Therapy—Uncomplicated Cases

Staphylococcus.....	8	62.5	37.5	0
Mixed.....	10	20.0	80.0	0

all the patients were cured. There have been many reports since then with cures varying between 75 and 90 per cent. Strains of various bacteria which are resistant *in vitro* are not necessarily resistant *in vivo*.

Our study was made in 208 cases of infections of the urinary tract. All the patients were hospitalized so that most careful clinical, biochemical and bacteriologic observations could be made. Complete urologic examinations, including pyelograms, were done on all patients. Examination of catheterized urine specimens in females and the three glass test in males were made daily, together with smears and stains. Cultures were taken frequently and the concentration of the drug in the blood and urine was determined twice a week. Our criteria for cure are repeated negative smears and stains of centrifuged specimens and negative bacteriologic cultures. Our results of sulfanilamide therapy in simple infections classified according to the infecting organism are reported in table 1: of the colon bacillus infections 80.6 per cent were cured, 16.4 per cent were improved and 3 per cent were unimproved; of the staphylococcal infections 62.5 per cent were cured and 37.5 per cent

were improved. We believe that the failure of these drugs in a certain type of bacterium in which the vast majority are successful is due to the difference in the strain rather than to insufficient concentration of the drug in the blood or urine or to the percentage of the drug conjugated. This was proved to our satisfaction²¹ in gonococcal urethritis, and the same is true with urinary infection. The rapidity of response is one of the most striking features noted. All the cured patients showed marked improvement and indeed often a complete disappearance of pus and bacteria within twenty-four hours. This occurs so frequently that we believe the drug should be changed if the patient has not reacted favorably within three days.

In cases of mixed infections the results are not so satisfactory as in those caused by a single organism. One bacterium is often completely eradicated while the other remains. This is particularly true in combined colon bacillus and staphylococcal infections. The colon bacillus disappears and most of the pus cells, but the staphylococcus often remains. Lockwood⁶ suggests that in mixed infections the staphylococcus may create environmental conditions which interfere with favorable action of the sulfanilamide on *Streptococcus haemolyticus*. It is also true that cases complicated with stones, residual urine and the like respond to a certain degree, but in very few is the infection completely eradicated.

A comparison of sulfanilamide with mandelic acid therapy is interesting. Some have reported as high as 90 per cent cures of bacillus infections with mandelic acid. In a series of nineteen patients with simple colon

GREATER PROPORTION EXCRETED IN FIRST 7 HOURS FROM BOTH NORMAL AND ABNORMAL KIDNEYS.

Chart 3.—Excretion of phenolsulfonphthalein and sulfanilamide in unilateral kidney disease. Single dose of 3 Gm. of sulfanilamide.

bacillus infections 65 per cent were cured and 35 per cent improved. After judging many reports, we conclude that mandelic acid and sulfanilamide each clear up from 75 to 80 per cent of uncomplicated colon bacillus infections. There are, however, certain circum-

21. Alyea, E. P.; Daniel, W. E., and Harris, J. S.: Sulfanilamide Therapy in Gonorrhea, *South. M. J.* 31: 395 (April) 1938.

stances in which one or the other is preferred. For infections complicated with prostatitis or seminal vesiculitis and the like, sulfanilamide is preferable because of its protean action. Mandelic acid acts only on the urinary infection and not on the associated focus of infection. On the other hand, mandelic acid is effective against *Streptococcus faecalis*, while sulfanilamide seldom destroys it. In infections of proteus and other urea splitting organisms in which it is usually impossible to obtain a urine with a p_H of 5.4, sulfanilamide

TABLE 2.—Sulfapyridine Therapy—Uncomplicated Cases

Staphylococcus.....	12	75	16.7	8.3
Mixed.....	6	50	50	0

is the drug of choice, as it is bactericidal in alkaline urine. Furthermore, for patients with damaged kidneys it is dangerous to use mandelic acid because of its renal irritation, while sulfanilamide is not irritating to the kidney. In acute infections of the kidney mandelic acid is rarely preferred because of its renal irritation, production of nausea, necessity of restricting fluids and the like. Elderly patients develop acidosis easily on mandelic acid therapy while sulfanilamide is tolerated well in the aged, with intelligent regulation of the dosage. Sulfanilamide acts quicker than mandelic acid and has a much larger range of specificity to bacteria. Braasch²² and others agree with these views. Because of the specificity of the drugs on different strains of bacteria it is often advisable to try first sulfanilamide and, if it fails, follow it with a course of mandelic acid. It must not be forgotten that mandelic acid administered with care is a most useful bactericidal agent. Ballenger¹⁶ has suggested hyperthermia plus sulfanilamide. This would coincide with the work, in vitro, of White.¹⁵ Ballenger first suggested associated hyperthermia in gonococcal infections and has subsequently reported its use in the treatment of nonspecific urinary infections.

Sulfapyridine has been used in the treatment of infections of the urinary tract. Melton¹² gives a clinical report of seventy-one cases. All but one of twenty-seven cases of acute pyelitis responded within from three to seven days. *Streptococcus faecalis* was found resistant also to sulfapyridine; only one case resulted in cure. Most of the infections with *Staphylococcus albus* and half of those with *Proteus* responded favorably. His dosage of 3 Gm. a day produced concentrations in the urine of from 46 to 190 mg. per hundred cubic centimeters. We have been using it in colon bacillus and staphylococcal infections (table 2). Among the cases of colon bacillus infections, 83.3 per cent were cured, 12.6 per cent were improved and 4.1 per cent were unimproved. Among those of staphylococcal infections 75 per cent were cured, 16.7 per cent were improved and 8.3 per cent were unimproved. This shows practically the same percentage of cures as that obtained with sulfanilamide in colon bacillus and slightly higher than that in staphylococcal infections.

The newest of the sulfonamide drugs used clinically are the thiazoles. DeEds,²³ working with phenothiazine, found that thionol, the active bactericidal agent

excreted in the urine, is markedly increased when the p_H of the urine is low. The dosage, therefore, may be cut in half when the urine is markedly acid. In a series of forty-nine cases, not classified according to bacteria, all but eight were cured or improved. The response was rapid, averaging thirty-five hours. Reports by Helmholtz,¹⁸ Herrell and Brown,¹⁹ Poole and Cook,²⁴ and Stirling²⁵ show that sulfathiazole is more efficacious against the staphylococcus than other sulfonamide drugs. Stirling reports eight cures of ten patients; the bacteria types are not mentioned. Poole and Cook report 65 per cent cures among fifteen patients with colon bacillus infection, seven with *Streptococcus faecalis* and five with *Staphylococcus aureus*. All of the five *Staphylococcus aureus* infections were cured. We have been using sulfathiazole in infections of the urinary tract and have found (table 3) staphylococcal infections cured in all of six cases; after treatment of nine patients with infections of staphylococcus and colon bacillus mixed, six, or 66⅔ per cent, were well and three were improved. This is, of course, too small a series from which to draw any conclusions.

DOSAGE

A considerable amount of interesting work has been done in vitro to determine the drug concentration in the urine necessary to render it bactericidal or bacteriostatic. Long⁷ and Vest¹³ show that various organisms need certain definite drug concentrations: *Bacillus coli* requires 200 mg. per hundred cubic centimeters, beta hemolytic streptococcus, 50 mg., and *Staphylococcus aureus*, 100 mg. Long suggested that each organism could be tested in vitro for each individual case and the particular bactericidal concentration determined. Mitchell²⁶ states that a concentration in the urine of 100 mg. per hundred cubic centimeters is needed to make the urine bactericidal and then 35 mg. per hundred cubic centimeters is needed to keep it so. Long and Vest suggest that a dosage of from 3 to 5 Gm. of sulfanilamide a day with fluids restricted to 1,200 cc. is bactericidal for most of the common organisms. We therefore started treatment of infections of the urinary tract in our clinic according to this regimen. In all these cases almost daily centrifuged specimens were

examined for pus and bacteria. Frequent cultures were taken and blood and urine concentrations determined twice a week. Table 4 A shows that 73.7 per cent of the patients with infections of colon bacillus were cured and 21 per cent were improved. In this group the concentrations in the urine varied from 75 to 250 mg. per hundred cubic centimeters, with an average of 117 mg. Concentrations in the blood averaged 5.7 mg. per hundred cubic centimeters. Many of the patients on this

regimen acquired objectionable toxic symptoms, which in several cases necessitated stopping the drug. In our outpatient clinic we noted that patients obtained equally good results with much lower concentrations of the drug in the urine. We then treated a series of patients in the hospital with a dosage of 3 Gm. a day but with fluids forced to 4,000 cc. a day. This, of course, cut down the concentration markedly to an average of 52.5 mg. per hundred cubic centimeters. Table 4B shows that 71.4 per cent of the bacillus infections were cured and 29.6 per cent were improved. We therefore conclude that *in vivo* the person's tissue or body reaction to the drug is of more importance than the concentration in the urine. This is in line with evidence found by Buchtel and Cook² and others that a prostatic infection may be cured when the concentration in the prostatic secretion is far below its bactericidal level. Furthermore, many staphylococcal infections were not cured even though its concentration in the urine was far above its "in vitro bactericidal level."

In another series we lowered the dosage of the drug to 1.8 Gm. a day and varied the fluid intake. Group 3, table 5 A, with a fluid intake of 1,800 cc. a day, had an average concentration of the drug in the urine of

TABLE 4.—Sulfanilamide Therapy

61.3 mg. per hundred cubic centimeters and a concentration in the blood of 3.5 mg. per hundred cubic centimeters. Group 4, table 5 B, had fluids forced to 4,000 cc. a day and averaged a concentration in the urine of 30 mg. per hundred cubic centimeters. The results in these two groups, as shown in table 5, are equal to and just as good as those in groups 1 and 2, table 4, which received the larger dosage. This agrees with our experience in the outpatient clinic, where equally good results are obtained on the small dosage of 1.8 Gm. a day with no restriction of fluids. These outpatients, however, are not included in this series because of insufficiently careful bacteriologic and biologic studies.

From the tables it is also apparent that the results in staphylococcal and mixed infections are the same with large and with smaller dosage. No patients failing to respond to 1.8 Gm. a day showed any improvement when the dosage of the drug was raised. Mitchell²⁶ has made similar observations. We are convinced, therefore, that a dose of 1.8 Gm. of sulfanilamide a day is just as efficacious in the treatment of infections of the urinary tract as larger doses. Furthermore, a concentration bactericidal *in vitro* is not necessary "in vivo." Hence fluids need not be restricted. Similar studies were made with sulfapyridine, 2 Gm. a day being used while the fluid intake was varied. Table 6 shows no difference in results between restricted and forced fluids. It is also evident that approximately the same percentage of colon bacillus infections was cured with

this drug as with sulfanilamide. Staphylococcal infections showed a higher percentage cured than there were with sulfanilamide.

There have been many reports of the use of sulfanilamide in pyelitis of pregnancy. From the obstetric department of Duke Hospital we selected seventeen

TABLE 5.—Sulfanilamide Therapy

patients treated with doses of approximately 4 Gm. a day. Biochemical and bacteriologic studies were not sufficiently complete to include these in our series. In this group sixteen patients were symptomatically well after six days of therapy. There were ten colon bacillus, four staphylococcal and three mixed infections. All but one showed a rapid and marked drop of temperature and clinical improvement within twenty-four to forty-eight hours.

All cases reported so far have been simple or uncomplicated. There is also a group of twenty-eight cases of urinary infections with complications such as stones, ureteral stricture and the like in which fourteen showed marked improvement; in nine of these fourteen cases there had been a nephrectomy or stones had been removed from the kidney, so that postoperatively they really became uncomplicated cases. This leaves only five of the remaining seventeen complicated cases which were improved on these drugs. There were fourteen that were unimproved. Our experience is therefore

TABLE 6.—Sulfapyridine Therapy

similar to that of others in that urinary infections complicated by other pathologic changes rarely respond to sulfanilamide therapy alone.

Our experience in the response of the infection in cases of post-transurethral resection to these drugs is similar to that of others;²⁷ namely, that it is of very little use in clearing up the urine. It may prevent mild postoperative complications. Preoperatively we

27. Gaudin, H. J.; Zide, H. A., and Thompson, G. J.: Use of Sulfanilamide After Transurethral Prostatic Resection, *J. A. M. A.* **110**: 1887 (June 4) 1938. Mitchell, Greay and Lucas.²⁸ Veit, Hill and Colston.²²

often prescribe it prophylactically to patients with sterile urine, but whether it really prevents infection is questionable.²⁸ In treatment of the bladder infection following transurethral prostatic resection we now delay the administration of the drug for a period of three weeks after the operation. In a good percentage of cases at this time the drug is of considerable help and we have seen many of these infections clear up within a period of forty-eight hours on 1.8 Gm. a day. The use of the small dosage in this group of elderly patients is of particular advantage.

Every one is now familiar with the toxic reactions of these drugs and nothing new can be added. All our patients tolerated with ease the drugs in the doses here recommended. Individual variations in tolerance of one drug or the other was encountered. At these low dosages it would be difficult to say that one was more easily tolerated than the other; it varied with different individuals.

In this study we have been struck with the accumulating evidence for specificity of reaction of these drugs to bacteria and different strains of the same type organism. The rapidity of response has also been mentioned. It has become our routine, therefore, to start a patient on the drug which we believe most suitable to his infection. If there is no favorable response in three or four days the drug is changed to one of the other sulfonamide drugs or to mandelic acid, depending on the organism and the patient. Because of our excellent results with sodium sulfanilyl sulfanilamide in sulfanilamide-resistant gonorrhea²⁹ we have used this drug in resistant infections of the urinary tract. A few of these cases responded favorably when all other sulfonamide drugs had failed.

Nothing has been said of the "old reliable" treatments of coccic infections with neoarsphenamine or the use of methenamine or many other well known and perhaps erroneously called urinary antiseptics. We can add nothing to what is already quite familiar. Recurrences have not been discussed because our reports may be unreliable. We know that there were seven recurrences in our series, but of course more may have occurred and the patients not reported to us.

SUMMARY AND CONCLUSIONS

1. The sulfonamide drugs are excreted by the kidneys in a manner exactly similar to phenolsulfonphthalein.
2. *In vitro* and *in vivo* studies show the specificity that the sulfonamide drugs have for different bacteria and different strains of the same bacterium.
3. Experimental studies *in vitro* are not necessarily entirely comparable *in vivo*.
4. The action of sulfonamide drugs in infections of the urinary tract depends more on the tissue reaction than on direct bactericidal action in the urine.
5. Mandelic acid is an excellent drug for infections with colon bacillus and *Streptococcus faecalis*.
6. A comparison of the colon bacillus infections treated with sulfanilamide and sulfapyridine shows practically the same, or 81 per cent, cured.
7. A comparison of the same drugs in staphylococcal infections shows that with sulfapyridine 75 per cent and with sulfanilamide 62.5 per cent were cured.

8. Response to the sulfonamide drugs is rapid, usually within two or three days.

9. Infections complicated by other pathologic changes do not respond as favorably as the simple infections.

10. A comparison of sulfanilamide and mandelic acid therapy in various types of cases shows that sulfanilamide is usually preferable.

11. Evidence shows that the high drug concentration in the urine usually thought desirable is not necessary for cures.

12. A dosage of 1.8 Gm. of sulfanilamide a day with fluids forced produced as good results as 3 Gm. a day with restricted fluids. The same is true with sulfapyridine.

13. Many patients cannot take the large doses with restricted fluids, but the recommended small dosage is easily tolerated by all.

SULFATHIAZOLE

A REPORT ON CLINICAL INVESTIGATIONS

GRAYSON CARROLL, M.D.

LOUIS KAPPEL, M.D.

AND

BRANSFORD LEWIS, M.D.

ST. LOUIS

Sulfathiazole, a derivative of sulfanilamide, was submitted to us for clinical investigation. Laboratory and animal experimental work indicated a low degree of toxicity and a high degree of protection against many virulent organisms, especially the staphylococcus, pneumococcus and gonococcus. This study includes 200 controlled patients. The drug was administered orally in 0.5 Gm. tablets to adults, smaller portions being given to children and babies. The sodium salt was given intravenously, a 1 Gm. ampule dissolved in 100 cc. of sterile distilled water injected slowly. The powder was used locally, sprinkled generously in infected wounds or introduced by insufflation into cavities.

A study of the absorption, dosage, toxicity and effectiveness of the drug follows:

ABSORPTION

The absorption of the thiazole compounds when given by mouth is quite variable, much more so than that of sulfanilamide or sulfapyridine. For example, one patient receiving 6 Gm. daily had a concentration in the blood of less than 1 mg. per hundred cubic centimeters. On the other hand, 4 Gm. administered to another adult patient was sufficient to maintain a concentration of 6 mg. per hundred cubic centimeters in the blood. The experimental work with animals indicates that a large amount of the drug is often recovered from the feces when the blood concentration is low, indicating most probably that the drug remains unabsorbed in some instances. It is therefore important to know the concentration of the drug in the blood of patients who are not responding favorably to the usual dose; if the concentration is less than 5 mg. per hundred cubic centimeters, the dose by mouth should be increased

From the Urological Department of the St. Louis University School of Medicine.

Read before the Section on Urology at the Ninety-First Annual Session of the American Medical Association, New York, June 12, 1940.

For this study sulfathiazole was made available by the Department of Medical Research of the Winthrop Chemical Company, Inc., New York.

to produce a satisfactory effect. The peak of blood concentration occurs with sulfathiazole in about four hours after administration and begins to decline after six hours. For example, an adult patient suffering of staphylococcal cortical abscess of the kidney was given 2 Gm. of sulfathiazole at 9 a. m., and blood concentrations were reported as follows: at 11 a. m., 2.1 mg. per hundred cubic centimeters; at 1 p. m., 5.2 mg.; at 2 o'clock, 5 mg., and at 3 o'clock, 4.2 mg. This is of clinical importance, indicating that the dosage of the drug should be spaced every four to six hours throughout the twenty-four hours in cases of serious involvement. After a single oral dose of 4 Gm., 1 Gm. is recovered from the feces and urine in the first twenty-four hours, 2.5 Gm. in forty-eight hours and some traces are found as late as seven days after administration.

DOSAGE

The usual prescribed dose for an adult is two 0.5 Gm. tablets orally every six hours. In the more severe cases a larger amount may be given with impunity. We have given as much as 14 Gm. daily with no harmful effects; one woman was given 1 Gm. of the sodium salt dissolved in 200 cc. of sterile distilled water intravenously, together with 6 Gm. orally in twenty-four hours; a blood concentration of 17 mg. per hundred cubic centimeters was obtained and there were no ill effects. Superficial lesions such as boils, abscesses, abrasions, ulcers, urethritis, pyelitis and cystitis require smaller amounts than do the deep-seated lesions such as cortical renal abscesses, pulmonary abscesses, abscesses of the liver, septicemia, osteomyelitis and meningitis.

The necessity of administering the drug in doses sufficient to bring about the therapeutic effect cannot be overemphasized. Deaths and failures have come to our notice analyses of which indicated definitely that sufficiently large doses had not been given to obtain the therapeutic effect. The medication, when tolerated, should be continued for a week or ten days after all clinical evidences of the disease have disappeared. The experimental work with animals performed by Lloyd Jones of the Bacteriological Department of St. Louis University indicates that positive staphylococcus cultures could be obtained from the tissues of animals coming to autopsy two weeks after administration of the drug over a fourteen day period. Children tolerate the drug well. Six grains (0.4 Gm.) daily was given in the milk formula to a 20 day old baby suffering from staphylococcal septicemia, from which he recovered. We have given children larger doses than those indicated by Young's rule. For example, children from 2 to 5 years of age have received 2 Gm. daily. In a child aged 2 years receiving 1 Gm. a blood concentration of only 0.1 mg. per hundred cubic centimeters was maintained and when 2 Gm. was given the blood concentration was held at 5 mg., with resultant recovery from staphylococcal pyelitis. No ill effects have been noted in elderly patients or in those with poor kidney function. Caution should be used, however, in treating patients with known liver and kidney deficiency, since the drug is eliminated through these organs. Sulfathiazole is best tolerated with food in the stomach and has been given beneficially with diluted hydrochloric acid rather than with the alkalis so often administered with sulfanilamide.

TOXICITY

Fifteen per cent of patients receiving sulfathiazole have complained of various drug symptoms, and in a

considerable portion of this group the drug had to be discontinued because of the severity of the reactions. Pain in the abdomen, nausea, vomiting, headache, anorexia, melancholia, weakness, cutaneous rash, diarrhea, undue excitability and nervousness have been the chief complaints. A peculiar conjunctivitis, unique for this drug, was observed by us after we heard it discussed by Perrin Long in his series. Acetyl concretions have been noted in the bladder, ureters and kidney pelvis of the experimental animals following administration of sulfathiazole, but no instance of concretions or anuria has been encountered in our series. Unusual concentrations of the crystals, causing marked cloudiness in the urine, have been noted, but increased fluid intake and a reduction or discontinuance of the drug caused this to disappear promptly. Red blood cells, albumin and casts have been noted in a small percentage of patients receiving the drug. It is to be noted that, should concretions appear, they, like those formed by sulfapyridine, are not opaque to the x-rays and are not affected by a change in the pH of the urine but are dissolved in distilled water at a temperature of 106 F.¹ The treatment, therefore, for scanty urine or complete anuria is withdrawal of the drug, forcing of fluids and cystoscopic lavaging of the kidney pelvis with hot sterile distilled water.

EFFECTIVENESS

Our clinical series includes many forms of infections in the urinary tract and also infections affecting other tissues treated in collaboration with attending physicians in other fields. We have found that the drug is effective against the staphylococcus, pneumococcus, gonococcus, *Streptococcus faecalis*, *Aerobacter aerogenes* and, to a less extent, *Bacillus proteus* and *Bacillus pyocyaneus*.

Since infections due to the staphylococcus have been notoriously resistant to all previously known medication, our chief interest has been centered around this organism. Chronic urethritis, in which the staphylococci are found on careful examination enmeshed in the shreds, has responded in three or four days to small doses of the medication. Infections of Cowper's gland and prostatitis have yielded in the acute phases, but permanent cures have not resulted in the majority of cases of chronic prostatitis treated. In infections due to residual urine or retarded flow of urine, such as cystitis due to neurogenic bladder or prostatic hypertrophy, diverticulitis, pyonephrosis and even urethritis, the urine did become culturally clear, but invariably the infection returned if the cause of the retarded flow was not corrected.

The promptness with which the infections accompanying renal, ureteral and bladder calculi are eradicated will prove to be of great benefit in preventing recurrences.

Staphylococcal septicemia, perirenal abscesses and abscesses of the renal cortex have responded favorably to the medication, but in each instance surgical drainage was instituted as usual. Staphylococcal pulmonary abscesses, osteomyelitis and acute multiple arthritis of staphylococcal origin were among the conditions that responded favorably. Postoperative wounds of staphylococcal origin and stitch abscesses have cleared up in forty-eight hours after administration of the drug.

1. Carroll, Grayson; Shea, John, and Pike, George: Complete Anuria Due to Crystalline Concretions Following the Use of Sulfapyridine in Pneumonia, *J. A. M. A.* 114: 411-412 (Feb. 3) 1940.

Boils and carbuncles have yielded promptly, and the recurrence of boils has been prevented. In all instances of infection of the urinary tract in which free drainage has not been instituted, recurrences have been most prevalent.

One of the most remarkable results has been obtained in the treatment of lesions about the penis, on which the powder of sulfathiazole was applied locally twice daily. Old Ducrey infections cleared up within four days. Herpes responded to local treatment in three days. Gonorrheal infections in the male and female, involving all sorts of complications, have responded more promptly and have shown less tendency to recur than after either sulfanilamide or sulfapyridine therapy. A more detailed report will probably be given by Dr. Roger Deakin of St. Louis, who has carried out carefully controlled studies. Pouring powder into an infected pyelotomy or ureterotomy wound has proved very useful. Only a few of the cases of acute epididymitis that were under treatment have responded well to the medication.

Far afield from urology, but of value nevertheless, is the effectiveness of the drug against impetigo in the nursery. Dr. P. J. Manion and Dr. Hollis Allen of St. Louis conceived the idea of putting the powder of sulfathiazole in the bath soap used in the nursery and thus completely eliminated impetigo in the nursery. When this practice was discontinued because of a temporary inability to obtain the drug, the impetigo reappeared. Local application of the powder on the weeping lesions of impetigo produced favorable response within forty-eight hours.

The in vitro investigations of Dr. Justina Hill² are reported as follows:

The action of sulfathiazole as present in urine after administration of the drug, as compared with the action of the same amount added to normal voided urine, showed a striking advantage in favor of the former. This indicated possibilities of changes of sulfathiazole during passage through the body which deserve further consideration.

The fact that all of the drugs tested have direct action in urine against small inocula is confirmed, and the limitations of antibacterial action are emphasized. The much larger amounts of sulfathiazole which may be expected in urine as compared with sulfanilamide and sulfapyridine and the intensification of the action of sulfathiazole by passage through the body indicate the possibility that sulfathiazole will be a more valuable urinary antiseptic than either sulfanilamide or sulfapyridine.

The comparative effect of sulfanilamide and sulfathiazole in vitro was reported by Charles H. Rammelkamp and Chester S. Keefer³ in the April issue of the *Proceedings of the Society of Experimental Biology and Medicine* and reveals that when ten or more organisms were added to the blood without any drug and incubated for forty-eight hours there were at least 10⁸ organisms present at the end of twenty-four hours. With sulfanilamide the same was true. Sulfathiazole, however, showed bacteriostatic and bactericidal properties. The number of organisms actually decreased during incubation. This decrease was striking even when as many as 100,000 organisms per cubic centimeter were used.

The bacteriostatic actions of the thiazole derivatives of sulfanilamide on bacteria in broth cultures shows the following:⁴

Three new thiazole derivatives of sulfanilamide have been studied with respect to their bacteriostatic action upon microorganisms. These compounds were found to be superior to sulfanilamide and sulfapyridine in their inhibitory actions upon pneumococci types I, II and III and beta Streptococcus haemolyticus group A in concentrations as low as 5 mg. per cent. Concentrations of 1 mg. per cent proved the new derivatives to be more effective against the gonococcus than the parent compound and sulfapyridine. The methyl and phenyl derivatives were found to be markedly bacteriostatic for Staphylococcus aureus. Sulfanilamide and sulfapyridine exhibited a moderate degree of inhibition upon the latter organism.

Dr. Barlow⁵ concurs in this. From the observations of others and from our clinical experience we have found it apparent that the sprinkling of powder into an infected wound or on a lesion is of definite value. Since most open abrasions and wounds of the skin are infected by the staphylococcus, the sulfathiazole used in powder form may prove of great value at this age, when injuries are so common.

SUMMARY

Sulfathiazole has proved clinically effective in a very positive manner against staphylococci, gonococci and pneumococci. Recovery has resulted following its use in renal abscesses, carbuncles, furunculosis, osteomyelitis, septicemia, ulcers of the penis, pyelonephritis, impetigo and other infections.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. ALYEA AND ROBERTS AND
DRS. CARROLL, KAPPEL AND LEWIS

DR. CHARLES A. W. UHLE, Philadelphia: In the management of every case one must differentiate between clinical cure and bacteriologic cure. The first cycle of action in chemotherapy is the production of a bacteriostatic phase in which symptoms ameliorate or completely subside but culture still remains positive. This calls for medication well into the symptom-free period if there are no untoward toxic effects, with perhaps a repetition of the course at periodic intervals. The ignorant or uncooperative patient, believing himself cured, will stop treatment. He then becomes a carrier and a social menace. In an analysis at the Philadelphia General Hospital of twenty cured cases of gonococcal urethritis treated with sulfapyridine, Drs. Knight, LaTowsky and Uhle found that the average number of carrier days was 17.7 with a range of from two to fifty days. In our ambulatory patients treated with sulfapyridine there was a high percentage of mild toxicity, whereas with sulfathiazole the toxicity was negligible. At the Philadelphia General Hospital crystalline precipitates of sulfathiazole in the papillae of the kidney and free crystals in the pelvis and ureter have been found at autopsy of pneumonia patients. In a recent analysis of pneumonia patients treated with sulfapyridine and sulfathiazole, Dr. Flippin has demonstrated that where high conjugated radicals are found crystalline precipitation is most likely to occur. Blood level determinations thereby seem to assume added importance in guiding the patient through an uncomplicated convalescence. Many of the more elaborate tests are not regularly indicated, however, when lower dosage is maintained in ambulatory patients. We have studied various forms of acute gonorrhea treated with sulfapyridine. Cures have averaged 92 per cent; the average time of cure as evidenced

by repeated cultures was forty days. These patients received 3 Gm. of sulfapyridine a day for an average of eleven days.

DR. ROGERS DEAKIN, St. Louis: Two years ago the male genito-urinary section of the Washington University Clinics undertook an intensive study of male gonorrhea. Of 474 unselected men applying for treatment during a twenty-two month period only forty-seven (10 per cent) have been lost; 62 per cent have already been cured after satisfying our tests of cure. These include various provocative tests, a minimum of four negative cultures and a period of observation averaging well over four months. Twelve per cent of the group are still under treatment; the remaining 15 per cent have been closed without proof of cure because of reinfections, transfer to other treatment agencies, or other reasons. We have found a type of work sheet most helpful in keeping the clinic personnel acquainted with what was happening to our cases. These charts serve as constant visual reminders to every one concerned of how good any treatment actually is. The personal equation is almost entirely eliminated because of tangible laboratory result or case disposition posted each time a patient is seen at his weekly visit. The almost complete absence of side reactions with sulfamethylthiazole which Dr. Carroll and his co-workers mentioned was particularly striking. Our experiences with side reactions in sulfathiazole have been the same, although we have not been impressed with any correlation between therapeutic response and blood concentration. One of the charts illustrates a method which we are using to check the validity of our results. The percentage of negatives obtained in three different treatment routines has been plotted for a nine week period. The percentage differences have been subjected to the test of significance each week; i. e., if the difference between two percentages (expressed in standard deviation units) is less than 1.96 the difference is not significant. A difference this large might occur five out of a hundred times merely by chance. If the difference is greater than 2.58 the difference is significant, in that it would occur from chance less than once out of a hundred times. It will be noted in each comparison that the differences are above the significant level between the second and sixth weeks. It is fair to assume that the early differences in therapeutic response can be attributed to the different drugs used and that at or about the sixth week the normal defense mechanism of the body against the gonococcus becomes the predominant factor in cure.

DR. W. RAY JONES, Seattle: One who has looked into such a bladder remembers that tuberculosis is localized in islands and is not a general infection in the beginning. In urethral gonorrhea infection begins in islands also and is limited. Infection is in that island: Why does it not spread to the touching surfaces? The infiltration has involved the mucosa and submucosa, so that it is almost one homogeneous mass. Infection is continued; as one island recovers another reinfects it; this way one locally may recover and be reinfecting several times before there is final complete recovery. A section of a gonococcus infected sinus showing islands located in the submucosa explains the why of reinfections and why the sulfanilamide group drugs are more efficient in treatment than is local therapy. Local therapy kills the organisms on the surface but does not touch the ones down in the little groups scattered about. A higher power section shows one of those infected islands breaking out through to the surface to reinfect. Here is an epithelized canal with the gonococcal infection down below the surface and the gonococci localized in that. It is breaking through the epithelized surface to bring infection back after a seeming cure. Sulfanilamide reaches not only the surface organisms but also those in the deeper localized islands of infection.

DR. REED M. NESBIT, Ann Arbor, Mich.: I wish to discuss the paper of Drs. Alyea and Roberts as regards the site of action of the sulfanilamide compounds. It was of interest to me to see a patient come into our clinic on whom we had previously performed bilateral urethral transplantation for carcinoma of the bladder. He had an acute gonorrheal urethritis and prostatitis. We gave him sulfapyridine and he got well by culture as well as by stain in five days. The urinary concentration in that case did not cure him.

FURTHER EXPERIENCE WITH DIVINYL ETHER (VINETHENE) ANESTHESIA

REPORT OF 2,050 ADMINISTRATIONS

HUBERTA M. LIVINGSTONE, M.D.

GERALDINE A. LIGHT, M.D.

A. FAUSTEENA HEIDRICK, M.D.

AND

VERA N. KABLE, M.D.

CHICAGO

Since the introduction in 1930 of divinyl ether as an anesthetic agent by Leake and Chen¹ and the preparation of the pure drug by Ruigh and Major,² there have been numerous reports in the literature dating from the study by Knoefel and his co-workers³ as to the chemical and pharmacologic properties of this substance. The clinical reports dealing with divinyl ether have appeared more frequently from Canadian, English and German authors. Since first used on human beings (themselves) by Gelfan and Bell,⁴ the larger series of cases in this country have been reported, among others, by Goldschmidt, Ravdin, Lucke, Muller, Johnston and Ruigh,⁵ Bourne and Sparling,⁶ Marvin,⁷ Beach,⁸ Ravdin and his co-workers⁹ and Feldman and Cartin.¹⁰ In a previous communication from this institution 335 administrations were reported. Since vinethene has, in our experience, become increasingly popular, a report is being made of our clinical results.

This study covers a total of 2,050 consecutive administrations. It was the only anesthetic used in 325 instances and was used as an induction agent preceding ether in 1,703 instances; the remaining twenty-two administrations represent vinethene inhalations supplemental to nitrous oxide-oxygen, ethylene-oxygen, avertin with amylene hydrate, and spinal or intravenous evipal soluble anesthesia.

SUBJECTS AND PROCEDURE

Since vinethene was the only anesthetic agent employed in 325 instances, we feel that an analysis of these administrations is of particular importance. The patients ranged from 10 months to 61 years of age, as follows: less than 1 year two, from 1 to 9 years 259, from 10 to 19 years forty-eight, from 20 to 29 years eight, from 30 to 39 years four, from 40 to 49 years two, from 50 to 59 years one, and 61 years one. The sex ratio was 152 female and 173 male. The operations performed are seen in table 1. Myringotomies, extractions and incision and drainage of abscesses are particularly frequent, although a rather wide variety of minor surgical procedures is included.

The preoperative condition of these patients was very variable. Some of the preoperative complications were as follows: A high percentage of the myringotomies and some other operations were performed on patients who had acute infections of the upper respiratory tract. Included are instances of acute sinusitis, streptococcal throats, acute tonsillitis, asthma, sniffles since birth,

bronchiectasis and other suppurative lung lesions, including a bronchopleural fistula. One patient had a previous laryngectomy, another a recent mastoidectomy and jugular vein ligation. Two had postpoliomyelitis flaccid paralysis of the legs and abdomen with some involvement of the respiratory muscles. Several patients had abscesses of the jaw. One had marked cervical adenopathy.

Two patients were classified as in poor condition because of brain lesions. Another had cyanosis and a stiff neck and in addition had had an acutely involved appendix removed twelve hours previously. One patient in fair condition had vinethene approximately three weeks after removal of a brain tumor and at the time was receiving sulfanilamide. Four had streptococcal meningitis and one had a questionable meningitis; three had lead encephalopathy; two had cerebral agenesis, and a patient with brain tumor was semicomatose but restless.

Eleven patients were recorded only as "acutely ill." Three were called "fair surgical risks." No details were given on these. Anemia and malnutrition were marked in three each. Three had acute hemorrhagic nephritis and another had sugar in the urine, 1 plus. One was jaundiced and another was very obese. One had poly-cystic kidneys.

Among cardiac abnormalities were a loud systolic murmur, a congenital condition of the heart and two instances of chronic rheumatic heart disease. Two patients had congenital syphilis. Two had eaten within three hours before anesthesia. Packs were removed from patients within twenty-four hours following various major surgical procedures. Among other individual complications were a hemolytic streptococcus septicemia, erysipelas, poliomyelitis with marked irritability, chickenpox and three cases of scarlet fever.

Premedication.—Many patients received no premedication. Eight received atropine, four morphine and atropine, three atropine, three pentobarbital sodium and one each soluble phenobarbital, and codeine and atropine. It was found to be particularly unnecessary and inadvisable to give premedication to those patients who were to be ambulatory immediately after anesthesia. Increased salivation seemed to be much less frequent than when we first employed the drug in 1936. Salivation occurred occasionally, but much less frequently

than with ether. Selective premedication may be employed, if desired, when patients are to be hospitalized. It is of interest to note that the one instance of nausea preceding anesthesia occurred in an adult after morphine premedication.

Method.—Anesthesia was induced by the open drop technic, using two thicknesses of cotton stockinet on a wire frame mask. It was felt that the surface on which the vinethene was dropped should not come in contact with the skin or mucous membranes in order to avoid a burn. The correct use of a wire ether mask, of a type corresponding to the Schimmelbusch mask, obviated this hazard. The eyes were protected with a moist pad of cotton batting. The dropper tip was held close to the mask to prevent loss by evaporation in the air before the drops reached the vaporization surface. The rate of administration was slow, between those of chloroform and ether. Air was permitted free access under the mask during induction. The patient was usually advised to count aloud. Consciousness was rapidly lost, and usually there were no manifestations of an excitement period. Table 2 shows the time required for loss of consciousness, which in 262 patients varied from twenty-five seconds to five minutes, the maximum number requiring around one minute. Vinethene may be administered by other methods, including the closed system with oxygen and the soda lime absorption technic, although such administrations are not reviewed in this report.

A variable quantity of vinethene ranging from 1 to 25 cc. was necessary for loss of consciousness, as is illustrated by the chart. It is evident that in the majority of instances only a small quantity of the drug was required for loss of consciousness.

Difficulties of Induction.—Complications are enumerated in table 3. Two of the children who had marked excitement entered the outpatient department screaming and kicking, and this persisted until after anesthetization. Both children were quiet and cooperative after anesthesia. The remaining patients exhibited no untoward symptoms, and color, respiration and cardiac response were normal. Obviously not all of the complications were attributable to the anesthesia.

Maintenance.—This was in no instance of long duration, the longest two periods being forty-five minutes. Ten were between thirty and thirty-nine minutes in

Amount of vinethene required for loss of consciousness.

length, twenty-one between twenty and twenty-nine minutes, fifty-three between ten and nineteen minutes, 114 between five and nine minutes and 125 five minutes or less. The required amount of vinethene varied considerably, depending particularly on the length of time of anesthesia and the general resistance of the patient. Five required less than 5 cc., nineteen needed 5 to 9 cc., 120 from 10 to 19 cc., eighty-seven from 20 to 29 cc., forty-one from 30 to 39 cc., twenty-seven from 40 to

49 cc., fourteen from 50 to 59 cc., five from 60 to 69 cc., four from 70 to 79 cc., one from 80 to 89 cc., and two required 120 cc. Thus it is obvious that the average patient required only a comparatively small amount of the drug for short surgical procedures.

Maintenance was almost uniformly satisfactory. One patient with acute hemorrhagic nephritis, high fever and severe infection of the upper respiratory tract had a sudden apnea lasting sixty seconds and accompanied by cyanosis. This was rapidly remedied by two minutes of oxygen insufflation. Respiratory signs were of the greatest value in denoting the stage of anesthesia, maintenance being associated with a quiet, full, regular and only slightly accelerated respiratory rate, accompanied by a full and regular pulse rate and excellent color. The eyelids frequently remained open and the eyeballs active in the upper plane of surgical anesthesia. The pupil reflex was variable. In the deeper plane of surgical anesthesia the eyeball became more fixed. The pupil may dilate and the eyelids may be closed in this plane of anesthesia. There was good relaxation of the skeletal muscles. Mucous secretions were marked in one instance and suction was necessary in another. The incidence of increased mucous secretion was low, in no way comparable to that seen with ether. As with all other anesthetics, an adequate supply of oxygen or air and an unobstructed airway were found to be essential.

Recovery.—This was rapid in every instance, consciousness usually being present almost immediately

TABLE 2.—Time Required for Loss of Consciousness

after cessation of administration. Recovery was particularly free from untoward symptoms. Many of the patients awakened smiling as if from a normal sleep. One medical student stated that he "enjoyed the anesthetic." Several of the patients sat up at once and experienced no untoward symptoms.

In each instance in which nausea and vomiting occurred it was present immediately after the cessation of anesthesia, and in no case did it persist. One patient had slight convulsive movements lasting one or two minutes after suction was employed following a cystoscopy. There was no cyanosis present. Recovery thereafter was uneventful.

The patients cared for in the outpatient department were rational and able to be discharged almost immediately after the operation, but for conservative reasons and for fear some circulatory disturbance or other untoward symptoms might occur they were requested to rest for thirty minutes before discharge.

Most of these patients were seen at a later postoperative visit and there were no complications. Among the patients hospitalized there were no complications, unless a case of generalized urticaria occurring one day postoperatively had some relationship to the anesthesia. One patient died two weeks later of meningitis which was in no way related to anesthesia.

In spite of its pungency, no patient objected to the odor of vinethene. One physician stated that he was aware of no marked difference in the odor from that experienced during a nitrous oxide-oxygen anesthesia he had received on the same day.

VINETHENE AS AN INDUCTION AGENT

Vinethene as an induction agent before ether anesthesia has been very satisfactory because of the simplicity of apparatus and administration and the smoothness and rapidity of anesthesia. The absence of tight fitting apparatus is an advantage with those patients, particularly children, who resent such technic. We have employed

open drop vinethene induction preceding ether anesthesia for 1,703 patients, and this method has met with increasing popularity. It is of paramount advantage in situations in which a gas-oxygen induction is not available. The psychologic factor of sparing the patient a prolonged ether induction is important, and at the same time the toxic hazards of other nongaseous inhalation agents are avoided.

The operations performed after vinethene inductions covered a wide range of both major and minor surgery, including ninety-seven major neurosurgical procedures. Age varied from 6 months to over 70 years. Twenty-two patients were less than 1 year of age. Although the maximum number were in the 1 to 9 year group, over seventy were middle aged or elderly.

There were many preoperative complications, among the outstanding being increased intracranial pressure and numerous brain tumors, convulsions, cervical cord tumor, meningitis, chorea, several cases of hemolytic streptococcus throat, bronchial asthma, several instances of bronchiectasis, pulmonary tuberculosis, congenital syphilis, three cases of congenital heart disease and fourteen of rheumatic heart disease, marked myocardial damage, marked scoliosis, poliomyelitis with partial paralysis of the muscles of respiration, previous tracheotomy, alcoholism, nephritis, pyelitis and albuminuria. A few patients had been receiving sulfanilamide.

TABLE 4.—Induction Complications

Premedication	Patients	Slight Excitement	Moderate Excitement	Marked Excitement	Marked Mucus

Totals.....	1,703	144	79	28	54

Premedication varied, as can be seen in table 4. The combination of codeine and atropine was employed in 301 instances, atropine in 238 and no premedication in 974. The remaining 190 patients received morphine-atropine premedication or one of the barbiturate derivatives, either alone or in combination.

PREOPERATIVE ANESTHETIC COMPLICATIONS

The incidence of excitement during induction appears in table 4. Two patients had nausea and eight vomited during induction. A few vomited only after ether was

started. Five coughed during induction. Two of these had received atropine and one codeine and atropine. One who coughed had received no premedication but was seriously ill with a lung abscess.

During induction cyanosis was observed in four patients who had not received premedication and in two who had received codeine and atropine. Fifteen had cyanosis at intervals until large tonsils were removed and a better airway was established. This was true whether or not premedication had been given. One patient had apnea for one minute during induction, and another had slow respirations from codeine depression and required oxygen inhalations.

Fifteen had cyanosis only after ether was administered. All of these received oxygen, usually by catheter or mask but in one instance by intratracheal intubation. Eight were depressed from overpremedication and one of these required intubation; two had laryngeal stridor; two had deep cyanosis after atropine and ether; one had hiccups; an acromegalic patient was cyanotic after atropine and a very small amount of ether, and one patient had an apnea following a lumbar puncture.

Sixteen patients had marked mucous secretions only after ether was started.

TABLE 5.—Blood Sugar Determinations in Relation to Vinethene Anesthesia

Patient	Before, Mg. per 100 Cc.	After, Mg. per 100 Cc.	Difference, per Cent	Direction	Anesthesia Time	Comment
1	96.1	130.8	36.1	+	10 min.	Slight cyanosis
2	100.6	116.4	15.7	+	10 min.	
3	92.7	111.9	20.7	+	10 min.	Extreme cyanosis
4	73.6	102.8	29.7	+	10 min.	
5	67.8	71.2	9.7	+	10 min.	
6	90.4	135.6	36.4	+	10 min.	
7	100.6	101.7	1.0	±	10 min.	
8	73.5	71.2	3.1	—	10 min.	
9	102.7	120.9	17.7	+	10 min.	
10	109.6	115.3	5.2	+	10 min.	
11	125.4	152.6	27.7	+	10 min.	

Muscular tremors or convulsive movements were observed during eight inductions with vinethene. Three of these patients also had deep cyanosis and one had hiccups. Four recovered spontaneously and four needed oxygen inhalations. One of the latter definitely had vinethene overdosage. Mucus and cyanosis were present, and there was abolition of intercostal activity followed by a short period of respiratory arrest. The patient recovered rapidly with manual artificial respiration combined with intermittent mask oxygen under moderate pressure. All of these anesthetics were satisfactory with ether maintenance. All but two of the eight patients had received premedication, the patient with vinethene overdosage having had atropine and the rest a combination of codeine and atropine or morphine and atropine. One patient having had codeine-atropine premedication had an uneventful vinethene induction but had muscular tremors toward the end of an ether maintenance anesthesia.

Hemorrhage occurred in two craniotomies and in two tonsillectomy-adenoidectomy operations under ether anesthesia.

POSTOPERATIVE COURSE

There were fourteen postoperative deaths in this series. Twelve were due to intracranial lesions and occurred from one day to two months after operation. One patient died twenty days postoperatively of an intestinal obstruction. All of these deaths were unrelated to the anesthesia. The other death may have been associated with the anesthesia, although this is ques-

tionable. It was reported in detail in our previous communication.¹¹

Thirty-four patients who had tonsillectomy-adenoidectomy procedures had postoperative hemorrhage, none necessitating return to the operating room. This occurred from the day of operation to the eighth postoperative day. It is of interest that of those having received premedication eleven had hemorrhage during the first forty-eight hours, mostly occurring a few hours after operation; while two had hemorrhage from three to eight days later. Of those without premedication seven had hemorrhage during the first forty-eight hours, while fourteen had hemorrhage several days after operation. Hemorrhage was controlled mostly by packing. A few patients needed intravenous fluids, and three received blood transfusions.

Postoperative fever was observed in twenty-four patients. In twenty-two instances it was unrelated to anesthesia and in two instances it was very questionably related.

One patient undergoing extirpation of an acoustic neuroma had received atropine and vinethene and ether (intratracheal). Facial weakness and inability to talk and swallow immediately followed operation and bronchopneumonia developed, but complete recovery occurred. Three had cough and coryza postoperatively, two having had an infection of the upper respiratory tract before operation and one a bilateral pulmonary tuberculosis. One patient who had an inguinal herniotomy after receiving atropine had much mucus during operation and coarse rales postoperatively.

Two patients had postoperative cyanosis on the day of operation. One of these had considerable mucus during anesthesia and the other was a semistuporous patient with an intracranial lesion.

Twenty patients had emesis on the day of operation, and one who had received codeine and atropine had emesis for three days postoperatively.

Neurologic complications include an unexplained convulsion one day after removal of very large tonsils and adenoids, the facial paralysis mentioned, one carpopedal spasm of questionable etiology two days after a maxillary sinus operation and tonsillectomy and adenoidectomy, and two headaches lasting two days following administration of morphine and atropine, vinethene and ether.

Blood sugar determinations were made before anesthesia and again at the close of vinethene anesthetics lasting approximately ten minutes or soon after recovery. The Shaffer-Hartmann-Somogyi method of blood sugar determination was employed. Results of this study appear in table 5. Many large children are in this series. Of eleven patients, nine had an increase in blood sugar and two had no appreciable change. These figures suggest that a blood sugar rise comparable to that found with several other anesthetic agents occurs with vinethene anesthesia and that this may be greater in the presence of cyanosis. The values in this series are not alarming. Further work on this subject is indicated and is being undertaken at this time.

SUMMARY

From clinical experience in 2,050 administrations we feel that vinethene anesthesia, particularly for short operations when patients are to be ambulatory soon thereafter, and as an induction agent when indicated, has a definite place in the surgical armamentarium. The

11. Light, Geraldine; Ross, Mary A., and Fulton, Elizabeth: Clinical Experience with Divinyl Ether (Vinethene), *Anesth. & Analg.* 16: 167-170 (May-June) 1937.

simplicity of administration and the infrequency of complications when employed by experienced anesthetists warrant the serious consideration of its use. Vinethene makes an excellent general anesthetic agent for office and outpatient practice; however, as with all anesthetic agents, a suction device and a supply of oxygen and apparatus for its efficient employment should be available. Although no explosions or fires have thus far been reported, precautions must be taken as it is inflammable and explosive.¹² The use of this rapidly acting agent should have its place in war surgery, particularly in areas free from the fire and explosion hazard. Short, painful procedures can be satisfactorily cared for under this agent, and the rapid return to complete consciousness will lessen the postoperative care.

Clinical Notes, Suggestions and New Instruments

SUBACUTE BACTERIAL ENDOCARDITIS APPARENTLY CURED WITH SULFANILAMIDE

AMOS CHRISTIE, M.D., SAN FRANCISCO

Spontaneous remissions, frequently of several months' duration, are not unknown in subacute bacterial endocarditis but spontaneous recovery is extremely unusual. Recovery is so rare in fact that "the occurrence of authenticated recovery from bacterial endocarditis is highly questionable" according to Kinsella.¹ Nevertheless a recent review of the literature by Capps² summarized the more authentic cases of recovery. He cited eleven cases he had himself observed with survival for more than five years. However, he had seen no recovery since 1924.

The advent of sulfanilamide in the medical therapeutic armamentarium gave rise to great hopes for successful treatment of this disease. Many disappointments and a few triumphs seem to have resulted as our experiences increase.³ The subject

has been evaluated more recently by Spink and Crago,⁴ who reviewed the literature and reported twelve cases of subacute bacterial endocarditis treated with sulfanilamide. In ten cases the ultimate course was unaffected, one was temporarily improved and one patient was well after nine months. They came to the conclusion that the use of sulfanilamide in subacute bacterial endocarditis "is of doubtful value because of the nature of the focus of infection."

More favorable results have been reported by Long and Bliss,⁵ whose extensive experience with the use of the drug has perhaps allowed them to use doses which produce blood levels of free sulfanilamide in excess of that used by other observers. At any rate they report during a two and a half year period the use of sulfanilamide in sixty cases of this disease with five cases "apparently cured." Consequently they believe as the result of their observations that "every patient suffering from subacute bacterial endocarditis should receive intensive therapy with sulfanilamide." It is also their opinion that, "provided the treatment is tolerated, it should be maintained until 'cure' or death results."

On this basis and with these dicta the following case of subacute bacterial endocarditis was treated with gratifying results. It is my purpose in this paper to report this case in sufficient detail to leave no doubt as to the accuracy of the diagnosis with especial emphasis on doses of sulfanilamide used and length of time administered. These points are believed important factors in the apparent good results.

REPORT OF CASE

E. I. M., a white girl aged 17 years, entered the University of California Hospital on Feb. 25, 1939, because of twitching of the arms, legs and hands, fever, hematuria, pallor and loss

Rectal temperature.

of 25 pounds (11 Kg.). She had been perfectly well until at 7 years of age she developed severe tonsillitis and twitching of the extremities. A diagnosis of chorea was made and the tonsils and adenoids were removed. The chorea recurred in four months and lasted intermittently for two years. At 9 years of age the patient developed "scarlatina" with a red rash, slight fever, no desquamation, and exacerbation of her chorea. At 11 years of age she again had scarlet fever, this time with desquamation and nephritis, and she was said to have developed heart murmurs at this time. Eight months before entry, at 16 years of age, she developed anorexia, fever, lethargy and vomiting and lost 25 pounds. For the past five or six months she had had red elevated nodules on her arms and legs. For two months prior to entry she was under the care of a private physician who observed a "hectic" fever, progressive anemia, an apical systolic murmur, and red blood cells in the urine. A blood culture taken at the time was negative but she became worse in spite of two blood transfusions. The remainder of the history is noncontributory.

On admission to the hospital the patient appeared poorly nourished and anemic. There were carious teeth. The tonsils were clearly removed. Petechial hemorrhages were found over the lower extremities.

The point of maximum intensity was diffuse in the fifth interspace 9.5 to 10 cm. from the midsternal line. This represented definite enlargement to the left. No thrills were felt. The heart sounds at the apex were accentuated, the second more than the first. There was a loud systolic murmur heard in the mitral area and widely transmitted particularly to the axilla. No diastolic murmur was heard. The rate was rapid. The blood pressure was 101 systolic, 68 diastolic. The spleen was palpable two fingerbreadths below the left costal margin.

4. Spink, W. W., and Crago, F. H.: Evaluation of Sulfanilamide in the Treatment of Patients with Subacute Bacterial Endocarditis, *Arch. Int. Med.* 64: 228-248 (Aug.) 1939.

Blood cultures positive for *Streptococcus viridans* were obtained on February 25 and 28. The same organism was recovered from a urine culture February 27. *Streptococcus viridans* found in blood and urine culture had the following reaction: not bile soluble, acid formation in and coagulation of milk, acid produced in maltose, sucrose, lactose, trehalose, raffinose and salicin. There was no fermentation in inulin, mannite and sorbitol. Blood count revealed hemoglobin 54 per cent, red blood cells 2,740,000, white blood cells 10,100, polymorphonuclears 76 per cent. The icteric index was 30.5. The sedimentation rate was forty minutes for 18 mm. The Addis test revealed specific gravity 1.014, protein 0.5 mg., hyaline casts 60,000, granular casts 120,000, white blood cells 3,500,000 and red blood cells 6,000,000.

The electrocardiogram showed no evidence of myocardial damage or other abnormality, but x-ray examination revealed gross cardiac enlargement to the right and left and particularly marked left auricular dilatation.

At the time of admission the patient had a swinging temperature between 38 and 40 C. (100.4-104 F.). The pulse rate averaged 115. Three days after admission several small red areas over the left ankle were observed. These were tender and left a slight discoloration when they disappeared. No other embolic phenomena were observed.

A diagnosis of subacute bacterial endocarditis superimposed on an old rheumatic mitral valvulitis was made. On March

5,272,000. Urinalysis revealed only a slight trace of albumin. The sedimentation rate was one hour and forty-two minutes for 18 mm.

SUMMARY AND CONCLUSIONS

A case of subacute bacterial endocarditis with chronic foci of infection, chorea, hematuria, petechiae, organic heart murmur, splenomegaly, progressive pallor and weight loss and two blood cultures positive for *Streptococcus viridans* is "cured" apparently. Following large doses of sulfanilamide for fourteen days the patient became afebrile, had four negative blood cultures and showed steady improvement and no remission in a year's observation period.

It is hoped that the early diagnosis of subacute bacterial endocarditis in children and young people treated as energetically as was this patient will have the same outcome.

USE OF QUININE FOR RELIEF OF "NIGHT CRAMPS" IN THE EXTREMITIES

PRELIMINARY REPORT

HAROLD K. MOSS, M.D., AND LOUIS G. HERRMANN, M.D.
CINCINNATI

Painful tonic spasms of muscles in the extremities of middle aged and elderly patients who may show little evidence of serious structural changes of the peripheral blood vessels frequently cause the practicing physician considerable concern. These muscular contractions usually occur while the patient is at rest and are frequently referred to as "night cramps."

On the basis of reports of Wolf and Kennedy¹ regarding the effect of quinine hydrochloride on skeletal muscles in myotonia congenita and in myotonia atrophica, one of us (H. K. M.) administered quinine sulfate to a woman whose suffering from these "night cramps" in both lower extremities was of such intensity that she was afraid to go to bed. The rapid cessation of symptoms prompted a study in a group of patients both with and without evidence of organic changes in the peripheral arteries.

Since March 1939 clinical studies have been conducted in the Vascular Disease Clinic of the Cincinnati General Hospital to determine the effectiveness of quinine therapy on patients who gave a history of "night cramps" of sufficient frequency and intensity that relief could be readily appreciated. Fifteen patients were studied. Improvement to the point of complete cessation of pain was promptly noted within a relatively short period of time, often a matter of hours. Unfortunately it is impossible to create these spasms at will and thus evaluate the effectiveness of the drug under such experimental circumstances. However, many of the patients not only experienced quick relief with medication but repeatedly had exacerbations when the drug was withdrawn or, unknown to them, a placebo capsule was substituted. The following cases are examples:

REPORT OF CASES

CASE 1.—I. W., a woman aged 67 who was suffering from "night cramps," complained on March 23, 1939, of a continuous muscular spasm in the calf of the left leg when she was at rest during the preceding week. Quinine sulfate 3 grains (0.2 Gm.) in capsule form three times a day was prescribed. April 6 she reported that her cramps had disappeared completely within three days after starting the medication and had not returned. In order to establish a minimum therapeutic dose, one 3 grain capsule was prescribed morning and night with continued relief. In April a capsule of the same physical appearance but containing lactose was prescribed. She returned to the clinic one week later because of recurrence of muscle cramps in the extremities. Relief was again experienced with resumption of one 3 grain capsule of quinine sulfate twice a day. In a further attempt to arrive at a minimum dose, one 3 grain capsule was administered only at bedtime. She experienced mild cramps

21 sulfanilamide was started. The daily dosage was 0.2 Gm. per kilogram of body weight, or 8 Gm. Sodium bicarbonate 4 Gm. daily was given with the sulfanilamide. Fluids were kept to 2,500 cc. daily. In three days the blood titer was 10 mg. per hundred cubic centimeters of free sulfanilamide. The temperature was normal. On the sixth day the blood level was 19 mg. per hundred cubic centimeters. The same dosage for the ensuing two weeks maintained a blood titer of approximately 20 to 24 mg. per hundred cubic centimeters. The patient became very cyanotic, had slurred speech and at times was very garrulous and had mild delusions and hallucinations. She took her fluids well without vomiting and ate well during the entire course of treatment.

Blood cultures taken on April 4, 10, 17 and 21 were all negative and the patient was afebrile for fourteen days without the drug. The toxic manifestations of the medication disappeared and she was discharged from the hospital on April 21, 1939.

Since discharge the patient has made an uneventful recovery. She has gained 40 pounds (18 Kg.) and is afebrile. Her physician reports (Feb. 1, 1940) that at no time has she shown any sign or symptom of recurrence of the infection. The heart murmur persists but there is no enlargement. A recent blood count showed a hemoglobin of 90 per cent and red blood cells

in the foot without involvement of either leg. Quinine sulfate 3 grains twice a day was then considered her minimum effective dose. On three subsequent occasions, in August and November 1939 and March 1940, placebos were substituted. Repeatedly the symptoms recurred and were relieved when quinine sulfate was taken by mouth.

CASE 2.—O. H., a man aged 56, who came to the clinic Nov. 30, 1939, complained of severe cramping in both calves and thighs from three to six times each night. Quinine sulfate 3 grains was prescribed morning and evening with complete relief the first night and only one cramp before his next clinic visit, December 15. Since he had suffered with this discomfort for years and had experienced remissions for a week or more before, he was not convinced that the medication played a part in the improvement. Milder cramps reappeared intermittently and his dose at night was increased to 6 grains (0.4 Gm.), in addition to the 3 grain morning dose, with complete relief. By the end of January 1940 he was enthusiastic, and a placebo was substituted. On February 15 he stated that he had had very mild cramps between the time of his last visit and two nights before his present one when the cramps returned with all their former severity. He was returned to his routine of 3 grains each morning and 6 grains each evening with alleviation of pain. He still occasionally reports mild spasms which he can relieve by stretching without getting out of bed.

CASE 3.—R. B., a man aged 69, had for years experienced muscular contractions of the legs when at rest. Aug. 31, 1939, he stated that he had remained out of bed the entire preceding night because of an immediate return of cramps on lying down. Quinine sulfate 3 grains was prescribed in the morning and at bedtime, with immediate cessation of symptoms the first night. He continued to have relief until November, when, on his failing to keep an appointment, his prescription was not refilled. Marked contractions with pain returned in the absence of medication and disappeared when it was resumed. In January a placebo capsule morning and night was substituted and the "night cramps" reappeared. Again on quinine sulfate therapy he had no complaints when last seen in April 1940.

CASE 4.—D. M., a woman aged 69, had "night cramps" so severe that they recurred every time she returned to bed. She preferred sleeping in a chair. Early in March 1939 a 3 grain quinine sulfate capsule was given after each meal and at bedtime, with prompt and lasting relief until her supply became depleted one month later. The contractions that reappeared were of lesser severity than before. Medication was reinstituted but reduced to two 3 grain capsules daily, with disappearance of cramps and continued benefit. On two subsequent occasions in August and November 1939 her supply again became depleted and the painful contractions reappeared, the second time severely. Instead of reestablishment of quinine therapy at this point, placebo capsules were administered. There was no change in one week. Quinine sulfate then replaced the placebo, with prompt relief. In January 1940 the patient's medication was discontinued and there has been no apparent need of it to date.

COMMENT

Though the relief after medication was consistent in all cases, many of them, in contrast to those described, continued without symptoms when a placebo was substituted or the drug discontinued. Their status was therefore impossible to evaluate. The coexistence of paresthesias and pain of vascular disease did not influence selection of patients provided "night cramps" were present. Intermittent claudication, when present, persisted despite disappearance of tonic contraction of muscles that occurred at rest. The pharmacology of quinine has been adequately discussed by Wolf,¹ Harvey,² Weiss³ and others.⁴

It is thought to act at the myoneural junction and appears to be the pharmacologic antagonist of prostigmine, relieving spasm in the myotonias and increasing the distress of myasthenia gravis.

CONCLUSION

Following the successful use of quinine by Kennedy and Wolf in the rare conditions myotonia congenita and myotonia atrophica, quinine sulfate was administered for relief of the common condition known as "night cramps." Fifteen cases were studied. A beneficial effect was noted in all. In some cases no return of symptoms followed cessation of medication or substitution therapy. A sufficient number, including the four cases reported, showed repeated exacerbations on a placebo and remissions when medication was resumed, indicating the value of the drug in this rather common form of muscular spasm. Further investigation as to the mechanism of action is being pursued.

GRANULOCYTOPENIA FOLLOWING INGESTION OF CAUSALIN

FRANCIS H. McGOVERN, M.D., DANVILLE, VA.

In spite of fairly widespread knowledge that the use of aminopyrine is always fraught with danger, the drug continues to take its toll. This situation is due first to indifference on the part of the physician, secondly to ignorance of the content of proprietary preparations and thirdly to difficulty in adequate legislation. Causalin,¹ a compound composed of equal parts of aminopyrine and hydroxyquinoline, is suggested chiefly for the relief of rheumatism and arthritis. Since the concept of acquired drug sensitivity causing profound reactions of the blood cells and hemopoietic tissues has been proposed, causalin has been repeatedly identified among those drugs which appear to be an etiologic factor in granulocytopenia.

An additional fatal case is here reported of extreme granulocytopenia following the ingestion of large doses of causalin over a period of a month.

REPORT OF CASE

An unmarried woman, aged 34, despite the warnings of her physician, had been taking six capsules of causalin daily over the period of a month. The history of no other medication was obtained. For the past twelve years she has been under the care of various physicians and clinics for a severe disabling chronic atrophic arthritis. She had used the drug the previous year with no apparent harm. The present illness started suddenly thirty-six hours before admission to the Memorial Hospital. She complained of severe sore throat, swelling of her neck, difficulty in swallowing, extreme malaise and high fever.

On admission her temperature was 105.6 F., respiratory rate 22, pulse rate 84. She was rational but appeared extremely toxic. She talked and swallowed with difficulty, owing to the markedly edematous and hyperemic pharyngeal structures. No ulcerations were present in the mouth or pharynx. Externally the neck was swollen but no glands were palpable. There was a chronic purulent otitis media on the left side. The heart, lungs, abdomen and extremities were negative to examination. The laboratory reported 315 white cells per cubic millimeter with no evidence of a granulocyte in the stained smear. The hemoglobin was 75 per cent and the red cell count 3,790,000. She was given Ringer's solution intravenously, with 10 cc. of pentnucleotide every four hours, concentrated liver extract intramuscularly and a 250 cc. blood transfusion late the day of admission. At midnight the white blood count was 500; the granulocytes were completely absent. Twenty hours after admission the patient had a convulsion and died. Postmortem examination was not performed.

COMMENT

The toxicity of aminopyrine contraindicates its use. Unlike sulfanilamide, its dangers overbalance its benefits and should be replaced by other analgesics or antipyretics. All physicians should be acquainted with the drugs incriminated in producing granulocytopenia and other hematologic disturbances.

ULCEROGLANDULAR AND PULMONARY TULAREMIA
TREATED WITH SULFANILAMIDE

J. M. JOHNSTON, M.D., PITTSBURGH

This case of ulceroglandular and pulmonary tularemia is reported for several reasons which make it of unusual interest, one of which is the fact that sulfanilamide was administered.

A youth aged 20, a farmer and miner, while hunting, Nov. 1, 1939, shot a chicken hawk which was feeding on a dead rabbit. He picked the hawk up when it was not quite dead and it pecked him on the third finger of the right hand. He did not touch the rabbit. The wound did not bleed. In three days the finger became swollen and a localized abscess was opened by his home physician. A chronic ulcer appeared at this site which in the next two months eventually healed. In January 1940 a swelling appeared in the right axilla which was progressive but never painful; fever was present, a loss of weight from 159 to 127 pounds (72 to 57.6 Kg.) occurred and a constant nonproductive cough appeared. There were no chills. The wound in the finger broke down several times but eventually healed, leaving a depressed firm scar.

The patient was sent by Dr. Lee Martin of Burgettstown, Pa., to the Mercy Hospital in Pittsburgh on April 18. At this time his temperature was 101.6 F., the white blood cells numbered 14,700 and the hemoglobin was 68 per cent (Haden-Hauser). The rest of his story was not significant. The urine was essentially normal. Physical examination showed the healed ulcer in the third finger of the right hand and a large fluctuant mass in the right axilla measuring about 10 cm. in diameter. The patient looked chronically ill and coughed constantly. There was considerable dyspnea necessitating elevation of the head of the bed. Examination of the chest showed absence of breath and vocal sounds in the left lung field, from the level of the eighth rib downward in the axilla and higher posteriorly. The percussion note was flat. Examination otherwise was essentially negative. Aspiration by needle of the axillary mass produced about 8 cc. of turbid yellow fluid which on culture was sterile both for ordinary organisms and on culture for tubercle bacilli. X-ray examination of the chest on April 19 showed extensive consolidation of the left lower lobe together with a small area of infiltration in the right lower lobe. By thoracentesis on April 23 250 cc. of greenish yellow fluid was obtained for diagnosis. It was evident that a great deal more fluid was present. Repeated blood cultures showed no growth. Culture of the pleural fluid showed *Pasteurella tularensis*. A macroscopic agglutination test for *Pasteurella tularensis* was positive on April 19 at 1:160 and on April 24 at 1:80. Sputum showed only an occasional hemolytic streptococcus and mixed oral bacteria. *Diplococcus pneumoniae* and *Pasteurella tularensis* were not isolated from the sputum.

Sulfanilamide, 1 Gm. every three hours, was begun on April 18 and continued in decreasing doses until, on April 26, a total of 36 Gm. had been given. The temperature within three days of admission had dropped to normal and remained so with slight variations. Forty-eight hours after all sulfanilamide had been discontinued, that is on April 28, there was a transient rise in temperature to 101 F., which disappeared spontaneously without further medication on April 30.

The patient was sent home without further aspiration May 12 weighing 133 pounds (60 Kg.), a gain of 6 pounds (2.7 Kg.) during his hospital stay, and having had a normal temperature for twelve days. He was seen June 17, at which time there was still dullness to percussion over the left side of the chest, but stereoscopic roentgenograms showed no evidence of fluid and almost total clearing of the lung fields. Fluoroscopic examination in various positions showed no restrictions in the movements of the diaphragm. The patient had gained 25 pounds (11 Kg.) in the month since discharge, was free from fever and was clinically well, and the right axilla showed only a small, firm, deep area of induration about the size of a pea.

COMMENT

The points of especial interest here are three: (1) the unusual way in which the disease was contracted, (2) the unusual length of time from infection until the appearance of pulmonary disease and the relative chronicity of the pulmonary lesion and (3) the possible influence of treatment. It is not unlikely that

the patient was seen at a time when spontaneous defervescence was about to occur. Nevertheless, rapid clinical improvement ensued immediately following the use of sulfanilamide. During the subsequent rise in fever the drug was purposely withheld, in spite of which a prompt drop to normal occurred. One cannot know whether sulfanilamide was of value or not. One point supporting the idea that some benefit was derived is the fact that while *Pasteurella tularensis*, a pyogenic organism, was recovered from the pleural fluid, empyema did not occur.

Therapeutically another question arose: whether to evacuate the pleural fluid or to allow it to remain. Because of the chronic nature of the pulmonary process, the known beneficial effect of allowing pleural effusion to remain in the chest in tuberculosis, and the continued absence of clinical signs of empyematous change, only the diagnostic thoracentesis was done. I believe that the good end result justified the reasoning here.

SUMMARY

A case of ulceroglandular and pulmonary tularemia exhibited several unusual features and several problems in therapy. Whether or not sulfanilamide influenced the clinical course is open to question. I am of the opinion, however, that the pleural effusion was a beneficial phenomenon and that, under similar circumstances, it should be left in situ as long as evidences of pleural suppuration do not occur.

PERITONITIS AND APPENDICITIS

CLINICAL LECTURE AT NEW YORK SESSION

ERWIN R. SCHMIDT, M.D.

MADISON, WIS.

John of Arderne¹ in 1370 wrote treatises on "passio iliaca" (either appendicitis or intestinal obstruction). Fernel² in his book *Universa Medicina* published in 1554 described a case of acute appendicitis with perforation. Laurence Heister³ described an abscess in the vermiform process of the cecum in his book *Medical, Chirurgical and Anatomical Cases and Observations* translated by George Wirgman in 1755. In 1757 M. Mestivier² reported on "Observations on a Tumor Near the Umbilical Region on the Right Side Produced by a Large Pin Found in the Vermiform Appendix of the Cecum." In his *Lectures on the Morbid Anatomy of the Serous and Mucous Membranes*, published in 1836, Thomas Hodgkins² says:

The partial inflammation of the peritoneum in the iliac fossa is sometimes set up by disease in the appendix caeci. If this be inconsiderable, it may merely give rise to some very limited partial adhesions; at other times, the appendix having been perforated by ulcerations, occasioned by the lodgment of the fecal concretions in its cavity, extravasation takes place, and inflammation of a more severe and serious kind is originated. Even in these cases nature sometimes succeeds in limiting the inflammation to a part of the right side; but it is at other times diffused over the whole abdomen, is accompanied by symptoms of the most serious nature, and quickly proves fatal.

In 1886 Reginald H. Fitz² in the *Boston Medical and Surgical Journal* in a paper entitled "Perforating Inflammation of the Vermiform Appendix with Special Reference to Its Early Diagnosis and Treatment" felt

From the Department of Surgery, University of Wisconsin Medical School.

Read in the Surgical Division of the General Scientific Meetings at the Ninety-First Annual Session of the American Medical Association, New York, June 11, 1940.

1. Garrison, F. H.: *An Introduction to the History of Medicine*, Philadelphia and London, W. B. Saunders Company, pp. 148-149.

2. Major, R. H.: *Classic Descriptions of Disease*, Springfield, Ill., and Baltimore, Charles C. Thomas, 1932.

that pathology in the appendix was the primary disease in what was commonly called typhlitis, perityphlitis and perityphlitic abscess. His paper could have been written today. Three fifths of the cases showed a fecal concretion as the local cause. Termination by resolution occurred in one third of the cases of typhlitis and perityphlitis. The chief source of danger in the peritonitis was its spread, and more than two thirds of the patients died in the first eight days. Recommended were opium treatment, rest and liquid diet in small quantities frequently repeated. The abscess was opened sometimes as early as the fifth day, usually later. Forty-seven per cent were operated on in the second week and 26 per cent after the third week. In the *Quarterly Cumulative Index Medicus* for 1936 there are 500 papers listed.³

The subject has occupied medical attention for many years. There is still no agreement. Orr⁴ says "Unfortunately a unanimity of opinion does not exist among surgeons concerning the operative and nonoperative treatment of peritonitis due to appendicitis." The discussions, papers, research and clinical experience still leave the subject unsettled in general, yet most individuals feel that their method is the best. The incidence of deaths due to appendicitis per hundred thousand has been steadily increasing in the United States. In the *Spectator* for Aug. 3, 1933, a table of deaths from appendicitis is shown covering the years 1910 to 1932 inclusive from sixty cities. It began with 13.3 per hundred thousand, reached 18 in 1929 and 1930 and in 1932 was 15.7. Individual cities went as high as 46.9 per hundred thousand and some other cities were as low as 1.5 per hundred thousand. The *Spectator* of Aug. 27, 1931, shows a mortality of 59 per hundred thousand in one city for the year 1930. Comparing these figures in the same paper, in 1929 Korea had 1.9, Cairo 3.1, Singapore 3.1, Port of Spain 7.4 and San Juan 5.4 per hundred thousand; England and Wales 7.1, Scotland 10, Irish Free State 5.2, Northern Ireland 5.2, New Zealand 7.2 and the city of Mexico 9.3. These are very interesting statistics.

The problem of appendicitis and peritonitis can be simplified by briefly discussing those aspects about which there is some agreement. Later we can turn our attention to controversial points. In general, an acute appendicitis in which the pathologic condition is in the appendix should be operated on. There will be a varying mortality because of:

1. Difficulty in making an accurate diagnosis. (In a series of 330 cases of acute appendicitis,⁵ acute appendicitis with abscess and acute appendicitis with perforation, we were correct in 76.9 per cent of the acute cases, 76.19 per cent of the cases with abscess and 90.625 per cent of the cases with perforation.)
2. Difference in severity due to type of organism. (Streptococcal infection is much more serious.)
3. The fact that every series of surgical cases has a mortality rate just due to the surgery, independent of the pathologic condition. (The cases should be listed by the type of pathologic change found and not by the preoperative diagnosis. Many a chronic or subacute case will creep into the series and improve the results, or cases with a pathologic condition outside the appendix will be included and give a higher mortality.)

The conditions mistaken for acute appendicitis are numerous. An analysis of the 330 cases mentioned shows that in 277 cases of acute appendicitis the clini-

cians agree with the pathologists in 76.9 per cent. In sixty-one cases classified as incorrect there was essential agreement, leaving only two cases, or 0.72 per cent, of error. In twenty-one cases with abscess, four cases were diagnosed at operation, an error of 22.81 per cent. Of the cases in which there was perforation, 90.625 per cent were correct. In fifty-three cases diagnosed as acute appendicitis, the pathologist on microscopic examination made a diagnosis of chronic appendicitis. Eight cases diagnosed as chronic proved to be acute. In one case a normal appendix was found. One case diagnosed as chronic inflammatory pelvic disease showed an acute appendicitis at operation. Other conditions that may cause mistaken diagnoses are meningitis, encephalitis, pneumonia, tabetic crises, pylorospasm, nonspecific ileitis, renal calculi, Dietl's crisis, lymphadenitis, spastic colon, cystic ovary, pelvic inflammatory disease, ectopic pregnancy, seminal vesiculitis, psoriasis and psoas abscess (Long's abscess), diverticulum of the bladder, strain of the abdominal muscles, hematoma of the abdominal muscles and Meckel's diverticulum.

Recognizing that the material discussed should be the same and human fallibility be eliminated as much as possible, the pathologic diagnosis should be as near

Fig. 1.—Appendicitis death rate (reprinted from Taylor, A. C., and Schmidt, E. R.: *Acute Appendicitis*, Internat. S. Digest 17: 195 [April] 1934).

perfect as we can make it. A simple classification would be as given in table 4.

In order to compare results, care should be exercised to select the cases pathologically so that the material in different series is the same. This would eliminate the great variation. The bacteriology is extremely difficult. Culture, isolation and identification of organisms require an expert bacteriologist. In most severe cases the bacteria present are multiple, while recovery usually occurs in those with a single infecting organism (Curreri, Wangenstein). The role of the gas forming organisms is difficult to interpret. From the bacteriology the clinical course cannot be foretold.

In considering an inflammation, its course is governed by definite factors: The dosage of the organism, the virulence of the organism and the resistance of the host. It will either clear up, progress and cause suppuration with later healing, or progress will lead to suppuration, extension to the blood stream, and death of the host. In a boil no one would consider cutting it before suppuration had taken place and nature built a wall of defense. A cellulitis is treated conservatively until it heals or suppuration takes place when it is incised and drained. An ulcer of the stomach is given rest; gastroenteritis is also treated with rest. A generally recognized surgical principle in many parts of the body is

to aid nature by enhancing the resistance, both local and general, of the host. A surgical procedure reduces the local and general resistance through dehydration and the production of a mild acidosis. This can be seen in respiratory complications following a general anes-

cent mortality while surgery gave 52 per cent, and operation and drainage more than doubled the amount of adhesions.⁶ These facts are generally accepted among surgeons.

Experimentally, a closed loop of intestine distends. A clinical example is found in intestinal obstruction.

6. Schmidt, E. R., and Taylor, A. C.: Acute Appendicitis in Dogs, Arch. Surg. 35: 65-70 (July) 1935.

With distention an anemia of the mucous membrane occurs. Reduced blood supply lowers resistance and permits an otherwise mildly virulent or common inhabitant of the mucous membrane to start the vicious cycle of inflammation. Wangenstein⁷ has shown that obstruction of the lumen is a factor in producing the inflammation. Hodgkins² and the very early writers² showed that fecaliths occurred in three fifths of the cases. What happens afterward depends on the local and general resistance of the patient.

One hundred per cent fatal peritonitis can be produced in dogs only if an opening 1 cm. long is made in the ileum several centimeters away from the ileocecal junction. Wangenstein⁷ has shown this, and Curreri⁸ in our laboratory has recently shown the same. Of fifteen dogs with such a peritonitis, fourteen died. The one dog that lived showed at laparotomy a complete closure of the opening by adhesions to adjacent loops of bowels and omentum. By means of Coli-Bactragen injected intraperitoneally before the bowel was opened, all the dogs lived. The later it is given after the bowel is opened, the less effective it is. Curreri⁸ used azosulfamide in sixteen dogs immediately after the ileum was opened and four dogs died—a mortality of 25 per cent.

Reprinted from the Monthly Bulletin of the Department of Public Health, City of Philadelphia, December 1932.

From this brief description clinically it is recognized that dosage and virulence of organisms with the resistance of the host are the factors determining the course of inflammation in various parts of the body. Experimentally lowered resistance of the mucous membrane initiates the inflammatory lesion of the appendix. To all intent and purpose these same factors work here. In other parts of the body attempts are made to aid nature to wall off the process. In the case of peritonitis from an appendicitis there are differences of opinion which may be considered as the radical forms, or the conservative with modifications as to the time of surgery.

It can be seen how complicated this subject has become. The variables are many: The surgeon and his judgment, the patient with all the factors that influence him, the virulence of the organism, the resistance, local and general, giving different pathologic conditions, produce innumerable combinations and possibilities which account for the great variation in the literature. The gradual increase in the mortality rate indicates that there is something wrong in the management of these variables.

In the management of 1,715 cases of acute appendicitis at the Wisconsin General Hospital and the Student

7. Bergh, G. S.; Bowers, W. F., and Wangenstein, O. H.: Perforation of Gastrointestinal Tract: An Experimental Study of Factors Influencing the Development of Peritonitis, Surgery 2: 196 (Aug.) 1937.
8. Curreri, A. R., and others: Results in Treatment of Experimental Peritonitis, to be published.

Infirmary of the University of Wisconsin, I want to point out some of our difficulties. In 806 cases of acute appendicitis diagnosed clinically at the Student Infirmary from 1924 to include 1939 there were no deaths; 2.4 per cent were ruptured. Operations were performed in 52 per cent; the remainder of the students were treated conservatively, sent back to their classes and advised to have an interval operation. Seventy-five per cent had symptoms less than twenty-four hours, and 90 per cent were between 18 and 22 years of age. Self medication was negligible.

In the Wisconsin General Hospital during this same time we had 909 cases diagnosed clinically as appendicitis in its various forms. Thirty-one per cent of the patients were over 30 or under 10 years of age. Only 55 per cent had symptoms less than twenty-four hours. Self medication was resorted to in 21 per cent of the cases, and 21.1 per cent were ruptured. In the uncom-

patients were operated on with a mortality of 17.4 per cent. Because we treat cases of rupture conservatively, many of these cases are very early cases of perforation with peritonitis—cases in which we considered the pathologic condition inside the appendix.

TABLE 4.—Classification of Appendicitis

1. Appendicitis with pathologic change in the appendix:
(a) Acute
(b) Subacute
(c) Healed
2. Appendicitis with pathologic change outside the appendix:
(a) Local peritonitis and cellulitis of cecum or mesentery
(b) Early spreading cellulitis
(c) General peritonitis
(d) Complications—early
(1) Rost abscess
(2) Pylephlebitis
(3) Subdiaphragmatic abscess
(4) Septicemia and pyemia
(e) Complications—late
(1) Adhesions
(2) Obstruction
(3) Sinuses
(4) Hernia
(5) Amyloid degeneration

The duration of the symptoms and the relation to the mortality show symptoms longer than twenty-four hours in only 34 per cent of the uncomplicated cases, 76 per cent of the rupture cases and 83 per cent of the fatal cases. The longer the symptoms had been present, the greater the percentage of ruptured appendixes. So, if the symptoms had lasted seven days, 65 per cent had ruptured.

Old persons and infants show a high mortality rate. From the first decade of life our mortality rate was 57.5 per cent; from 50 to 60, 56 per cent, and from 60 to 70, 66.5 per cent. In the student series where the greatest number, 90 per cent, were between 18 and 22 years, there was no mortality.

The last fourteen cases of ruptured appendixes were treated conservatively as usual, but in addition sulfanilamide was employed. Only one patient died, giving a death rate of 7.1 per cent, whereas the death rate was 19 per cent in all our previous cases.

In an analysis of 221 cases treated from 1937 to 1939 there were six deaths. In all of them appendixes were ruptured on admission, and the symptoms had been present on an average of three days. The causes of death were toxemia of general peritonitis three,

Fig. 2.—Section of appendix under low power.

plicated cases the mortality rate was 1.2 per cent, in the ruptured cases 19 per cent, giving a general mortality of 4.9 per cent.

In the Wisconsin General series 21.1 per cent were ruptured, 10.7 per cent showed a local or general peritonitis and 10.4 per cent abscess. Of the infirmary cases, 2.4 per cent were ruptured.

The self medication which plays such a prominent part in producing mortality was interesting. In 43.5 per cent of the rupture cases a laxative was taken, while rupture occurred in only 21 per cent of the untreated cases. The rupture cases with medication showed a mortality of 56 per cent, while all the rupture cases showed a mortality of 19 per cent. The cases of acute appendicitis in which laxatives were taken showed a mortality of 10 per cent, while the mortality in the whole series was 4.9 per cent. There were no deaths in the acute cases in which there was no perforation.

There were 192 cases of ruptured appendicitis in this series. Ninety-four cases were treated conservatively with a mortality of 20.5 per cent. This group includes several patients brought in moribund. Ninety-eight

thrombosis and embolism two, bilateral bronchopneumonia with effusion one. Four of these patients were operated on and two treated conservatively. Three patients were under 10 years of age and two over 50. Four of these patients were purged enthusiastically—two at the instigation of the family physician. One patient received chiropractic adjustments for four days prior to admission.

The causes of death in the whole general series are given in table 5.

Generally, one may say that appendicitis has been with us a long time. The mortality rate is increasing and needs the serious attention of the medical profession. The difference in the incidence between the various countries is extremely interesting and deserves serious thought and investigation. Certain data are generally accepted. An acutely inflamed appendix with the pathologic condition inside should be removed surgically. The diagnosis is not easy. The fundamental principles of inflammation which are applied in many parts of the body in the clinical management apply in the peritoneal cavity and the appendix. In order to compare results, the same type of cases, pathologically speaking, should be used. A simple classification is given. The mortality rate should not be the only yardstick in measuring the success or failure of a method, but the morbidity which follows should be included. The combination of mortality and morbidity serving as a method of measuring results will guide each individual as to the best method in his own particular case. Statistics are not obtained by wishful thinking, and memory is often convenient but very inaccurate and confusing.

In our series the analysis shows some of our problems. In 1,715 cases we had a mortality of 4.9 per cent. In the rupture cases it was 19.0 per cent, in the unruptured 1.2 per cent. In 806 students with 2.4 per cent of rupture cases there was no mortality. They came in early and were healthy young adults under careful medical care, so that 48 per cent were returned to classes in a short time. The very young and the aged do not stand infection very well. Laxatives are very serious and increase the mortality rate 400 per cent over the general rate and 300 per cent over cases of rupture in which laxatives are not used. The longer the symptoms are present, the greater the percentage of rupture cases. Chemotherapy both from clinical as well as from experimental evidence offers a great help. The mortality rate is due to infection and its sequelae and associated pathologic conditions present before the appendicitis.

From this it develops that the medical profession needs to do certain things from the medical point of view and for the laymen:

For the medical profession:

1. Stop the use of laxatives in the treatment of a possible appendical infection.
2. Recognize the lessons inflammation has taught us in other parts of the body and apply these to the appendix and peritonitis.
3. Be accurate in describing the pathologic condition and bacteria, so that comparisons may be made of methods and results.
4. Recognize the morbidity as represented by late complications as a part of the yardstick in evaluating results.

For the laity:

1. Conduct a campaign in the lay press by the local, state and national medical societies to teach that:

(a) Pain in the abdomen should not be treated by laxatives.

(b) Where the pain persists for an hour, medical attention is needed.

2. An effort should be made by the medical societies such as was done in Philadelphia to get the drug stores and pharmacists to aid in this campaign.

Council on Physical Therapy

THE COUNCIL ON PHYSICAL THERAPY HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORTS. HOWARD A. CARTER, Secretary.

MOORADIAN SHORT WAVE UNIT, MODEL C, ACCEPTABLE

Manufacturer: Mooradian High Frequency Laboratories, 137 Park Place, Bogota, N. J.

The Mooradian Short Wave Unit, Model C, is said to provide currents for the following therapeutic and surgical procedures: short wave diathermy applied by pad electrodes, spaced pad electrodes, cuff electrodes, electromagnetic induction cable, and diathermy applied internally by means of metal orificial electrodes; electrosurgery, fulguration and electrocoagulation, both monoterminal and biterminal. The unit is housed in a two piece walnut cabinet, the upper part containing the short wave generator and the lower providing storage space for the accessories which are supplied with the unit. The apparatus has an output of 300 watts at 15 meters and an input of 794 watts.

Mooradian Short Wave Unit, Model C

The output current for pads and cuffs is obtained from three terminals composed of a common terminal and two others; the choice of these terminals is determined by the spacing used. This duplex circuit feature together with a wide range tuning control is said to provide a flexible range of control with or without spacing.

Separate terminals and control are used for the electromagnetic induction cable.

The output terminals of the surgical circuit are inductively and capacitatively coupled to the main tank or oscillating circuit. A separate vernier condenser control is used in conjunction with the main tuning control to provide regulation of the surgical current. The tubes consist of two 311-T oscillator tubes.

Evidence submitted by the firm concerning deep tissue heating measurements was confirmed by the Council's investigation.

The Council's clinical investigation of the unit revealed that the unit gave satisfactory clinical service.

Cuffs

Technic: Cuff lengths, $19\frac{3}{4}$ inches. Cuff width, $2\frac{3}{4}$ inches. Average distance between cuffs, 7 inches. Average spacing under cuffs, three-fourths inch. Average thigh circumference, $19\frac{1}{2}$ inches. Average room temperature, 74 F. Average room humidity, 43 per cent.

Average Temperatures of Six Tests

	Cutaneous	Subcutaneous	Intramuscular	Rectal
Initial	91.86	94.83	99.36	99.7
Final	97.3	102.68	105.26	99.73

Coil

Technic: Four turns. Space between turns, $1\frac{3}{4}$ inches. Average thigh circumference, $19\frac{3}{4}$ inches. Average room temperature, 73 F. Average room humidity, 41 per cent.

Average Temperatures of Six Tests

	Cutaneous	Subcutaneous	Intramuscular	Rectal
Initial	91.03	93.65	99.35	99.86
Final	98.88	104.38	107.33	99.86

The Council voted to accept the Mooradian Short Wave Unit, Model C, for inclusion on its list of accepted devices.

HYPERTHERM FEVER CABINET ACCEPTABLE

Manufacturer: The Liebel-Flarsheim Company, 303 West Third Street, Cincinnati.

The purpose of the hypertherm is to produce and maintain artificial fever. The firm asserts that the apparatus is designed to operate completely by controlled, warmed, humidified air which circulates throughout the patient compartment.

The cabinet is said to be constructed of corrosion-proof metals; the cabinet proper is 72 inches long, 34 inches wide and 57 inches high. The head bracket is 12 inches long and 21 inches wide, and it supports a drain pan and pillow rest. The entire unit is mounted on casters. The upper part of the apparatus, or the hood which encloses the patient chamber, is constructed of aluminum, air insulated and supported with galvanized steel framework; this hood is hinged and counter-balanced for one-hand operation. A sponge rubber collar seals the opening in the hood for the head, and a towel rack permits towels to be conveniently draped around the patient's neck to reduce heat and humidity loss. Two large sliding doors, 11 inches by 22 inches, are placed on each side of the hood. For checking actual temperature, one door is designed for motion in a forward direction and gives a small opening. For full vision, inspection and quick cooling, the doors are moved toward the foot of the cabinet. Latches on each door prevent the patient from opening them on the inside. The patient compartment is illuminated during treatment, and a window in the head portion of the hood permits observation of the patient.

A hair mattress, the top of which is 36 inches from the floor, is placed on the table or lower portion of the apparatus and is covered with rubber sheeting.

The air conditioning system is mounted under the mattress framework; the mechanism consists of a large steam generating humidifier, a mixing fan and a small air heater. Air is circulated in this lower portion and is allowed to rise into the patient compartment by natural circulation. A simple thermostatic dry bulb control is used for selecting the temperatures desired in the cabinet and controls both the humidifier and the air heater, maintaining saturated conditions at all times. A main switch controls the entire unit. Water is supplied to the humidifier by means of a gallon bottle inverted on a feeder supply which keeps the level of the water constant in the humidifier and at the same time provides a visible gage of available water.

Hypertherm Fever Cabinet.

The firm states that a long series of wet and dry bulb tests over a full range of cabinet temperatures used showed a relative humidity of from 95 to 100 per cent. The energy input is a maximum of 14.5 amperes at 115 volts.

Two safety rubber-bladed fans are placed on brackets at the head of the cabinet. The fans are placed so that they will provide circulation over the patient's head during treatment; one can be placed to blow through the side door across the patient's body if an emergency arises. The head pan facilitates the use of iced cloths or ice on the face.

The rectal indicating thermometer is supplied as an integral part of the equipment and can be used throughout the treatment. This indicating instrument has a scale range of 90 to 110 F. and is equipped with a mirror for more accurate readings. Three standard 1½ volt dry cell batteries are used in series to supply the electric current for operating the mechanism. Switches and mechanism for adjusting the meter to zero, balancing the voltages and standardizing the calibration are readily accessible and plainly marked. The rectal applicator will retain its position throughout the duration of the treatment. The indicating instrument and rectal applicator permit all rectal bulbs to be interchangeable.

The firm submitted fifteen copies of charts made during treatments. Twelve of these show the induction period necessary on twelve patients; the other three show the constancy with which a patient's temperature might be maintained.

In the Council's clinical investigation, the Liebel-Flarsheim Hypertherm Fever Cabinet was used in a clinic acceptable to the Council for several months and was found to give satisfactory service. The temperatures of patients may be elevated to needed levels with reasonable safety and good control. Constant checks by means of a rectal thermometer proved the electric rectal indicating thermometer to be accurate.

The Council voted to accept the hypertherm for inclusion on its list of accepted devices.

Council on Pharmacy and Chemistry

PRELIMINARY REPORT OF THE COUNCIL

THE COUNCIL HAS AUTHORIZED PUBLICATION OF THE FOLLOWING
PRELIMINARY REPORT. PAUL NICHOLAS LEECH, Secretary.

CALCIUM MANDEATE AND CALCIUM MANDEATE-MALLINCKRODT CHEMICAL WORKS

Calcium mandelate has been presented for the Council's consideration by the Mallinckrodt Chemical Works as a form of mandelic acid therapy for urinary infections. It is claimed that this preparation is as efficient as the sodium or ammonium salts which are included in New and Nonofficial Remedies. The advantages claimed for calcium mandelate are (1) that it appears from present clinical evidence to be less likely to induce nausea, vomiting or other forms of gastric distress and (2) that it is tasteless.

Calcium mandelate was first used in the clinic by Schnohr,¹ who was gratified with the results which he obtained. According to Schnohr, this compound is broken down in the stomach to calcium chloride and mandelic acid. The calcium is excreted as an insoluble salt in the feces, while the free mandelic acid is excreted in the urine. The acidifying action of calcium mandelate is not as great as that of ammonium mandelate, but it produces a sufficient drop in pH to make the therapy effective. In Schnohr's experience doses of from 6 to 12 Gm. daily were well tolerated and urinary infections in eight cases were cleared as satisfactorily as with any other form of mandelic acid therapy.

These results were confirmed by Melton and Rosenheim.² In their series of thirty-two cases the urine became strongly acid within a short time, only four requiring additional acid therapy. The clinical results were considered to compare favorably with those obtained with sodium or ammonium mandelate. The calcium salt was more pleasant to take and without significant disagreeable effects.

Droller³ observed that the urine became acid about eight minutes after administration of calcium mandelate in thirty-one cases. No toxic symptoms developed and the clinical results were satisfactory.

Cailleux⁴ believes that the calcium and ammonium salts are equally effective and that such therapy is most excellent for urinary tract infections.

In the Council's discussion of this preparation, question was raised as to whether this product might cause any disturbance in the calcium level in the blood stream. It was concluded that this question could be answered only by extensive metabolic experiments. A further question was raised as to whether, in the use of calcium mandelate, the mandelate concentration in the urine is comparable to that when other solutions have been used. It was concluded that this point has not been definitely proved. The Council felt it not unlikely that calcium mandelate may be as effective therapeutically as other salts. However, in the absence of convincing clinical evidence on the points raised the Council voted to hold in abeyance the consideration of the drug and of the brand submitted by the Mallinckrodt Chemical Works to await the accumulation of further clinical evidence.

Cable Address - - - "Medic, Chicago"

Subscription price - - - : Eight dollars per annum in advance

Please send in promptly notice of change of address, giving both old and new; always state whether the change is temporary or permanent. Such notice should mention all journals received from this office. Important information regarding contributions will be found on second advertising page following reading matter.

SATURDAY, OCTOBER 19, 1940

IMPORTANT ANNOUNCEMENT

At this time The Journal is compelled to inform its readers that the work of the American Medical Association as a body, including its contribution in aid of the national defense, must suffer serious interference during the next two or three months. The Secretary and General Manager of the American Medical Association, the Editor of its publications, the Secretary of its Council on Medical Education and Hospitals and the Director of its Bureau of Medical Economics must be absent from the headquarters office during those months since they are required to attend, as defendants, their trial in the United States District Court for the District of Columbia on the indictment there returned against them and against the American Medical Association, the Medical Society of the District of Columbia, the Washington Academy of Surgery, the Harris County (Texas) Medical Society and fifteen prominent physicians in Washington, D. C. The indictment charges all defendants with having conspired to violate Section 3 of the Sherman Anti-Trust Act. The Association respectfully asks the indulgence of the medical profession and the public throughout the United States for any deficiencies which may result from this unavoidable and unfortunate condition.

When the American Medical Association was requested to assist in the national emergency now confronting this country, its House of Delegates voted unanimously and without dissent to give wholehearted cooperation and support. The officers, the headquarters office, the Committee on Medical Preparedness, the state chairmen and numerous other physicians have been and are now engaged intensively in that service, and they expect to continue therein. In advising physicians and the public of this apparent discouragement in the essential work that it has undertaken to perform, the Association desires to say that it will do its utmost to overcome all obstacles to medical preparedness. We assure the medical profession that it will never be said, either in criticism or in comment, that the Association failed its country in any hour of need no matter what obstacle might arise to

interfere with the otherwise expeditious and efficient service that this country deserves in this critical hour.

The Journal has indicated repeatedly the difficulties associated with medical mobilization and the nature of the work now being carried on to provide all the various arms of the government with physicians. Even though this work will be seriously hampered by absence from the headquarters office of some of the key men who have been charged with this duty, every possible method will be utilized to carry on the work as expeditiously as can be done. Plans are also being developed for the handling of correspondence, finance, personnel and all the other multitudinous affairs associated with the work of this great organization to the best extent of which the organization is capable, so that the medical world and the public may not suffer by this serious interference with the provision of medical service and the dissemination of knowledge of medical advancement.

EXTRAPLEURAL PNEUMOTHORAX

The simplicity and safety of intrapleural pneumothorax as a measure for collapsing the lung in the treatment of tuberculous cavitation is well known. In a number of cases, however, intrapleural space cannot be produced because of adhesions between the parietal and visceral pleural leaves; in some cases inadequate or contraselective collapse takes place; these conditions make imperative a search for other methods. Thoracoplasty is far more efficient than pneumothorax but is a major operative procedure, deforming and resulting in an irreversible state as far as the compressed lung is concerned. Extrapleural pneumothorax is a recently advocated procedure aimed to produce a selective extrapleural pocket to be maintained by air pressure. The method was first tried by Tuffier in 1891 for a pulmonary hemorrhage. He applied this technic in several cases and attempted to maintain the space by introduction of nitrogen gas. The results of the operation were disappointing because of the tendency of the lung to reexpand. The attempt to overcome this expansion led to various methods of plombage. The dissected extrapleural space was filled with fat (Tuffier), muscle, paraffin and other foreign bodies. None of the methods proved satisfactory either because of infection of the foreign material or because of rupture of the lung tissue. This led to the return to simple apicolysis advocated by Zorini (1932) and by Michelson.

Credit for the development of the technic and indications for the operation of extrapleural pneumothorax seems now to belong to Graf,¹ who in 1936 reported 107 personal cases, and to Schmidt,² who performed the same operation with slight modification in 155 cases (1937). The aim of the operation is to produce a

1. Graf, Walther: Ausblick auf neue Wege in der chirurgischen Kollapstherapie der Lungentuberkulose: Extrapleuraler Selektivpneumothorax und -oleothorax, Deutsche med. Wchnschr. 63: 4 (Jan. 1) 1937.
2. Schmidt, Walter: Gezielte Teilplastik, Pneumolyse, extrapleuraler Pneumothorax und Oleothorax als Methoden einer erhaltenden und schonenden operativen Kollapstherapie, Beitr. z. Klin. d. Tuberk. 88: 689 (Dec. 21) 1936.

selective collapse of the part of the lung involved, by means of an air pocket which is made by stripping the pleural layers off the inner surface of the ribs and intercostal muscle sheaths. An incision is made parallel to the vertebral border of the scapula, the fourth rib exposed and from 6 to 12 centimeters of it resected subperiosteally. Incision of the bed of the resected rib brings the dissecting finger on the endothoracic fascia. Dissection now follows carefully the line of cleavage between the parietal pleura and the endothoracic fascia. The stripping is carried out anteriorly down to the third rib, posteriorly to the sixth or seventh, and medially to the hilus. The operation is easily performed in the absence of extensive or firm adhesions. The wound is sutured hermetically. Air may be injected into the extrapleural pocket thus created at the completion of operation or twenty-four hours later. The postoperative care requires much attention if the operation is to be a success. The difficulties are principally due to the tendency of the compressed lung to re-expand and to a rapid formation of an exudate. Dolley, Jones and Skillen³ recommend daily fluoroscopic control and from one to four refills during the first week. Following this the patient is placed on a seven day schedule. The average amount of air given is 80 cc. The crux of the procedure is the maintenance of the space. Should the x-ray films demon-

strate progressive contraction of the pocket, oleothorax may be tried. Graf and Schmidt believe that every extrapleural pneumothorax must sooner or later be replaced by oleothorax. The mixture employed is 2.5 per cent cajuput oil with 10 per cent iodized poppy-seed oil in olive oil. From 7 to 10 cc. is injected at the first instillation and the quantity is increased daily until the pocket is filled with oil, on each occasion a corresponding amount of air being removed.

Hemorrhage, infection of the exudate, broncho-extrapleural fistula and emphysema may complicate the procedure. Dolley, Jones and Skillen endorse in the main the indications for extrapleural pneumothorax formulated by Schmidt and other workers. These may be divided into absolute, broad and conditional. The absolute indications are when (1) attempted intrapleural pneumothorax has been unsuccessful, (2) the cavities

are neither fibrotic nor stiff walled and are not more than 4 cm. in diameter and their involvement does not extend beyond the sixth rib posteriorly, (3) the contralateral lung is free of active tuberculosis and (4) the lesions are nonacute, relatively recent, limited in extent and present in a patient who is a fair or a good surgical risk. The broad indications are when (1) circulatory or respiratory function is only fair, (2) the cavities are somewhat fibrotic or of considerable size and located at the lung periphery, (3) the contralateral lung may be more or less extensively involved and (4) disease may be of a year's duration with widespread though not marked fibrosis. The conditional indications are (1) poor physical condition, (2) old stiff walled cavities in which thoracoplasty is contraindicated because of the size and position of the cavities and (3) the

existence of contralateral cavities. The operation is not intended to replace a selective thoracoplasty. Probably it will find its greatest usefulness in extensive bilateral disease when selective intrapleural pneumothorax is impossible, in less extensive and active disease when collapse therapy is urgently needed but pneumothorax is impossible or unsatisfactory, and when diaphragmatic paralysis is considered inadequate and a thoracoplasty carries too great a risk. It will also be preferable to thoracoplasty in the very young because of the deforming result of the latter and

in the very old because of the hazard of a major operation. The greatest merit of the procedure is the absolute selectivity of the collapse with preservation of tissue and the minimal disturbance caused by the operation.

A number of questions in connection with this procedure have not been answered. How long must the pneumothorax or oleothorax be maintained? Theoretically one might say until the lesion is healed, which may be one or two years or more. Graf believes there is no harm in leaving the oil permanently. The oil may be gradually aspirated. Is extrapleural pneumothorax a reversible procedure? Will the lung reexpand? Complete reexpansion is unlikely because of the greatly thickened parietal pleura and fibrosis induced by the oil.

Dolley and his associates have reviewed approximately 2,000 cases from twenty-seven clinics and have concluded that the extrapleural pneumothorax when performed for absolute and broad groups of indications will be instrumental in obtaining approximately 63 per

THE PLATFORM OF THE AMERICAN MEDICAL ASSOCIATION

The American Medical Association advocates:

1. The establishment of an agency of the federal government under which shall be coordinated and administered all medical and health functions of the federal government exclusive of those of the Army and Navy.
2. The allotment of such funds as the Congress may make available to any state in actual need, for the prevention of disease, the promotion of health and the care of the sick on proof of such need.
3. The principle that the care of the public health and the provision of medical service to the sick is primarily a local responsibility.
4. The development of a mechanism for meeting the needs of expansion of preventive medical services with local determination of needs and local control of administration.
5. The extension of medical care for the indigent and the medically indigent with local determination of needs and local control of administration.
6. In the extension of medical services to all the people, the utmost utilization of qualified medical and hospital facilities already established.
7. The continued development of the private practice of medicine, subject to such changes as may be necessary to maintain the quality of medical services and to increase their availability.
8. Expansion of public health and medical services consistent with the American system of democracy.

3. Dolley, F. S.; Jones, J. C., and Skillen, Jane: Extrapleural Pneumothorax, *Am. Rev. Tuberc.* 41:403 (April) 1940.

cent of sputum conversions. There is no procedure according to Graf that produces such dramatically rapid healing in properly selected cases and which at the same time may be attended by so many complications.

It may be argued that creation of an artificial space in the body is an unnatural procedure. The clinical results seem to indicate that the new procedure is a valuable addition to measures for collapse of the lung.

Current Comment

BRINKLEY ON THE BRINK?

According to a newspaper article from a Little Rock (Ark.) newspaper October 4 Dr. John R. Brinkley is having a little more trouble. Five cases are apparently pending against him in the federal court:

Charles F. Allen, administrator of the estate of Oliver S. McKibben, seeking judgment for \$104,200 for the alleged wrongful death of Mr. McKibben.

Billie Leon Ball, minor, by L. S. Ball, guardian, seeking judgment for \$35,000 for alleged wrongful treatment.

Charles F. Allen, administrator of the estate of Louis J. Masopust, judgment for \$261,270 for alleged wrongful death.

E. P. Lambert, administrator of the estate of Abner Johnson, seeking judgment for \$90,000 for the alleged wrongful death of Mr. Johnson.

Charles F. Allen, administrator of the estate of J. F. Crenwelge, seeking judgment for \$264,270 for the alleged wrongful death of Mr. Crenwelge at the Brinkley Hospital.

In connection with these cases, United States District Court Judge Trimble issued an injunction restraining Dr. Brinkley, his wife, Mrs. Minnie T. Brinkley, or their agents from compromising or attempting to compromise these suits pending against Dr. Brinkley in federal court in violation of the laws of the tribunal. The injunction was granted after Dr. Brinkley failed to appear in the federal court to give an oral deposition in the last of the cases mentioned. The judge is said to have stated that "If he [Dr. Brinkley] goes and compromises these cases while this injunction is in effect, I am going to put him in jail for contempt of court." Attorneys for Mr. Allen immediately filed a motion for default judgment under Rule 37 (d) of the new rules on civil procedure recently promulgated by the United States Supreme Court. The attorneys for E. P. Lambert in the Johnson case alleged that they had proof that Dr. Brinkley, through agents, was attempting to compromise the cases through threats to heirs of the deceased. They stated that Dr. Brinkley "is stalling for time to settle these suits around us," without permitting them to go to trial before a "fair" jury. The attorneys continued: "He is sending out his cohorts to attempt to settle these cases directly while the suits are pending in this court." They detailed these charges as follows: That agents of Dr. Brinkley have been busy since July 23, when Brinkley was "first notified to appear here for an oral deposition, attempting to reach a compromise with heirs of the deceased," and that Brinkley "was attempting to influence the heirs to file damage suits in their home towns." They stated that "He [Brinkley] would then settle these cases and come into federal court here and plead *res adjudicata*." Attorneys for Brinkley denied knowledge of the charges and defended Brinkley's absence by stating that they had never guaranteed any one at any time that Brinkley would be there. One of the attorneys stated: "I have

no control whatever over his actions. I notified him of the deposition notice, and that was all I could do." Perhaps these cases may yield the evidence which the Post Office Department seeks before it will deny the use of the mails to John R. Brinkley.

THE TREATMENT OF TETANUS

The therapy for tetanus has never been considered notably successful. Recently a new procedure has been reported by Spaeth¹ from the University Hospital, Iowa City, the results of which offer a favorable comparison with other methods previously employed. The routine used emphasizes systematic sedation, conservative surgical intervention, efforts to prevent pneumonia and the maintenance of an adequate fluid and caloric intake. Avertin with amylene hydrate, given rectally, or sodium amylal, given preferably to avertin with amylene hydrate in the presence of rectal irritation or incontinence and possibly in renal or hepatic disorders by any of the available channels of therapy (intravenous use limited to severe asphyxial spasms), or the two in conjunction, were found to effect a prompt and satisfactory control of neuromuscular manifestations of the disease. Control of spasms and the appearance of muscular relaxation ordinarily occurred within five to ten minutes, provided adequate doses were employed. The induction of severe cerebral depression indicated a grave condition, and persistence of convulsions despite intensive sedation made the outlook particularly serious. Spaeth recommends the prompt use of antitoxin in all cases of tetanus, regardless of the clinical picture or the duration of the disease. The frequent absence of local lesions and the possibility of atypical modes of onset counsel the prompt administration of antitoxin even when the diagnostic data are inconclusive. The intrathecal administration of antitoxin is rejected on the ground that it is based on an erroneous conception of the pathogenesis of tetanus. Intrathecal serotherapy may, moreover, contribute to a fatal outcome by causing excitement, serum meningitis and possibly cerebral or medullary edema. On the other hand, the intravenous procedure is recommended for routine use and the intramuscular for persons known or suspected to be sensitive to horse serum antitoxin. Patients with convulsions were given the entire dose at one time, one half being given deep in each gluteal region. For patients free from convulsions the gradual administration of serum is recommended. Surgical treatment of tetanus, the author thinks, is ordinarily not an emergency procedure and should not be employed until the patient has been given the benefit of adequate sedative and antitoxin therapy. When circulating antitoxin fails to neutralize toxins, a careful search for splinters or other objects may identify the focus of infection. Surgical exploration does not seem justifiable, if nail puncture wounds appear to be healed. In the presence of gas gangrene, the wide excision of involved cases and the use of sulfanilamide are indicated. The new treatment has been employed in thirty-three cases since 1933 with an equal number of controls. There were twelve deaths in the control group and nine in the new, a difference

1. Spaeth, Ralph: A Clinical Study of Tetanus, *Am. J. Dis. Child.* 60:130 (July) 1940.

which may be significant but requires a larger series of cases. In spite of these apparently improved results, Spaeth stresses the importance of active immunization by means of tetanus toxoid and especially of the value of combined tetanus-diphtheria toxoid in the immunization of children.

"THE ELASTIC ELEMENT" IN SICKNESS INSURANCE

A system of life or fire insurance can be a symmetrically built structure with mathematically accurate relations; the elements in the structure can be clearly defined. Fire and death are facts about the existence of which there usually is no dispute and the incidence of which can be calculated with a close approach to accuracy. Illness and its diagnosis and treatment are uncertain in their incidence, indefinite in their scope and character, variable in form and changeable in time. Any system of prepayment for medical service must be a structure with many loose joints and elastic sections that can be squeezed and stretched to meet incalculable changes. If income is fixed and payments to physicians are standardized through salaries, the elastic element must be the quality of the medical service. European writers on sickness insurance freely admit that it is always necessary to squeeze the service until it is rather thin and the physician's income until it is scant to get them into the limits set by insurance resources. Advocates of compulsory sickness insurance and types of contract medicine in this country deny or avoid all mention of this fact. They talk as if the income from insurance premiums were the flexible element that could be stretched to cover all required medical service. Somehow they never tell the prospective patients that the squeeze must really fall on the quality of the service. This is, nevertheless, so fundamentally true that any plan which promises "complete medical service" for fixed payments must sooner or later maintain financial solvency by reducing the quality or the quantity of the medical service and by skimping payments to physicians. The patients cannot realize the significance of deterioration in the quality of medical service. Diagnosis may become superficial, incompetent specialists may be hired or expensive types of treatment may be avoided and the patient will be none the wiser. The state and county medical societies that are experimenting with prepayment plans frankly face this fact and try to meet it honestly. They seek to introduce an elastic element into their structure that will not lower the quality of the service. The unit system lets the pressure fall on the physician's income, and the "deductible clause" puts a portion of the burden on those receiving the service. Similar elastic elements in other departments of the structure than that of service are financial rewards to those not using the service in any year and small payments for the first calls in any illness. Somewhere in every prepayment structure such elements of flexibility must be introduced just as they must be into a building or a bridge subject to incalculable strains. None of these devices have yet been demonstrated as wholly satisfactory, but any of them can be demonstrated to be far more desirable than the concealed use of diagnosis and treatment as the elastic element.

SIR HENRY HEAD—NEUROLOGIST

The death of Sir Henry Head from Parkinson's disease on October 9 at his home in Reading, England, at the age of 79 closes an eminent career. As early as 1889 Head, working in Hering's laboratory in Prague, began his fundamental reports on the functions of the peripheral nerves. His investigations on the cutaneous distribution of pain and tenderness in visceral disease showing that the segmentation of the cutaneous areas affected by the different viscera corresponds with that belonging to the root ganglions of the spinal nerves are known to every medical student. These areas are now known as "Head's zones." In 1903 he made the unique experiment of dividing his own left radial and external cutaneous nerves. The observations of the loss and restoration of sensation which he experienced, together with extensive subsequent investigations, led to a new classification of sensory paths. His work on peripheral sensation is therefore epochal and Head's name will always rank high in the history of neurology.

EMERGENCY LABELS FOR UNPASTEURIZED MILK

Pasteurization of milk, universally approved by physicians, health officers, milk producers and the producers of certified milk as well as by the American Association of Medical Milk Commissions, grows more widespread year by year. In many localities it is now illegal to distribute unpasteurized milk, except certified, for which pasteurization is permissive rather than mandatory. While equipment for pasteurization has been improved in many ways, it is still impossible to safeguard the pasteurizing plant against all the causes of breakdown. Situations may arise in which it is necessary to deliver unpasteurized milk in communities where pasteurization is required by ordinance. Such a situation is potentially dangerous, since it may be necessary to put unpasteurized milk in bottles labeled as if they contained pasteurized milk. Even if the label was changed for the emergency, few householders would be likely to note the change, since they would not be in the habit of reading the label daily. Among the causes for failure of pasteurization beyond the control of the operator listed by the New York State Department of Health¹ are flood, storm or other disaster resulting in failure of electric power over a wide area "making it impossible for operators of pasteurizing plants to pasteurize their milk supplies." To meet this emergency the New York State Department of Health has devised a collar to be slipped over the milk bottle bearing the warning that milk so labeled has not been pasteurized and that it should be boiled before using. The text of the warning is as follows:

Raw milk—Warning—Due to an emergency over which the dealer has no control, this product is raw instead of pasteurized as labeled. Play safe and boil before using.

According to the New York State Department of Health, "these notices are to be used only in case of widespread emergency. They should never be used when it is possible for dealers to have milk pasteurized at another plant. Health officers may obtain these warnings from the district health officer."

1. News Service, New York State Department of Health, Albany, Aug. 5, 1940.

MEDICAL PREPAREDNESS

In this section of The Journal each week will appear official notices by the Committee on Medical Preparedness of the American Medical Association, announcements by the Surgeon Generals of the Army, Navy and Public Health Service, and other governmental agencies dealing with medical preparedness, and such other information and announcements as will be useful to the medical profession.

WORK OF THE INDUCTION BOARDS

Already young men have registered for selective service, the drawings will soon occur, and the young men will be called by local draft boards previous to their call for attendance at induction stations. At each of these induction stations there is to be a board of medical examiners who will be responsible for determining whether or not young men will be actually assigned to camps and cantonments for training. During mobilization the usual flow of men will be from local selective service boards to induction stations for final examination and induction, then to reception centers for classification and other processing, then to the organizations, installations or replacement centers in which they are to serve.

The induction station serves the same purpose as the recruiting station does in times of voluntary enlistment. Therefore recruiting stations, augmented as required, will be used as induction stations. Corps area commanders are authorized to establish induction stations at any point in their areas. It has been estimated that from nine to twelve induction stations for each corps area will be sufficient, including at least one in every state, which would make about one hundred in all. In sparsely settled areas the induction station may consist of a number of physicians and army officers who will travel from place to place.

In each of these inductions there will be provided ample space, light and toilet facilities. During cold weather the rooms will be heated so that the young men who will be compelled to be nude during the examination will not suffer from cold. Special rooms will be provided for conducting eye, ear, nose and throat examinations, and there must be a room with a sink and toilet facilities for use as a laboratory. Corps area commanders are also expected to furnish necessary equipment where that is not available.

For the physical examination the procedure contemplates an eight hour day with twenty-five men examined every hour. It is believed that it will be found practicable to admit one man to the examining team every two minutes. This will permit ten minutes at the end of each hour for further examination and conferences on difficult cases. The order of the examination is as follows:

1. Laboratory examination of the urine and, when required, of sputum, blood smears and urethral discharges.

2. Withdrawal of blood for the serologic test for syphilis. Blood specimens will be obtained and subsequently tested in federal or state laboratories by personnel assigned by the United States Public Health Service.

3. Eye, ear, nose, throat and dental examinations. Registrants may remain clothed up to this point if desirable. From here on they must be completely nude.

4. Height, weight and chest measurements and examination of the bones, joints and feet. This may be done in one large or two small rooms. The room for the orthopedic examiner should be of sufficient size so that four examinees may be brought in at one time and put through the required movements.

5. General surgical examination.

6. Examination of heart and lungs, for which three rooms will be required, so situated that examiners will not be disturbed by outside noises.

7. Neuropsychiatric examination.

8. Checking of records by the chief of the examining board. At this time requests for x-ray, laboratory and other special examinations will be prepared and provision made when necessary for the examinee to be conducted to the proper army hospital or civilian institution for the examination. Arrangements for a local hospital or clinic to provide these facilities must be made by the chief of the board prior to beginning the examinations. In occasional instances proctoscopic, electrocardiographic and other special examinations may be required.

After registrants are accepted by local draft boards they will be sent for physical examination to medical induction boards. About one hundred such boards will be set up throughout the country, about half of them near army posts and stations. Each board will consist of three internists, one general surgeon, one orthopedic surgeon, two ophthalmologists, one otorhinolaryngologist, one neuropsychiatrist, one clinical pathologist and one dentist.

As explained by Colonel Love in *The Journal*, October 5, pages 1201-1202, the specialists to be assigned to such service will probably include civilian specialists as well as reserve officers, who will be on temporary duty. Civilian physicians will be on a per diem basis and will be used as long as their services are required. It has been proposed that they be paid at the base pay of major with allowances for travel and subsistence while on duty. Physicians preferred for this service are those who, on account either of age or of physical infirmities or because of reasons affecting their civil life, cannot go into military camp. It has been tentatively estimated that the time required for this service might approximate twenty to thirty days in the period between October 16 and February 1.

In order to aid the Army Medical Department in securing physicians for this service, the Committee on Medical Preparedness requests physicians who wish to volunteer to write at once to the Committee on Medical Preparedness, 535 North Dearborn Street, Chicago, marking the envelop "Induction Boards."

THE VALUE OF RADIOGRAPHY IN DETECTING TUBERCULOSIS IN RECRUITS

RAMSAY SPILLMAN, M.D.

New York

The cost of taking men with manifest tuberculosis into the armed forces is a timely subject for study. Certain lessons can be learned from the experience of the World War and the postwar period that it would be costly to ignore.

The physician who has served a term rating cases in the Veterans' Administration has the opportunity to acquire an insight into the problem of the compensation of the disabled veteran that cannot be gained anywhere else. I was thus engaged in 1920 and 1921. I have also had the opportunity to investigate the after-records of a group of members of the old Sixty-Ninth Regiment of the New York National Guard who were diagnosed as tuberculous on radiographic evidence by Dr. Lewis Gregory Cole but who in the absence of physical signs were mustered into the 165th U. S. Infantry. The material derived from these sources seems of sufficient importance to present in some detail.

The cost of compensation of veterans of the World War for tuberculosis is a matter of public record, but it seems far from being a matter of common knowledge. Table 1, compiled from the annual reports, is illuminating.

It is emphasized that the figures preceded by dollar signs are per month, not per year. They are for the last month of the fiscal year. Two columns require explanation for the uninitiated. Column 2, "Vocational Trainees, Section 2," refers to veterans who were receiving vocational training, the section 2 meaning that they were receiving a maintenance allowance in lieu of compensation, as distinguished from section 3, under which tuition and such expenses were paid but compensation was paid and not maintenance allowance. The section 2 trainees, who outnumbered the members of section 3 in the ratio of 92.7 to 7.3 (Annual Report, 1923, p. 391), were carried on a different roll and their number should be added to column 1 to show the actual figure for veterans receiving a subsidy for service connected disability.

It has not been feasible, from the annual reports, to run the figures back past 1922. The annual report for that year is a formidable document, comprising 659 plus xvii pages, twenty-eight charts and 143 tables, but it is surpassed in 1923, when there were 1,082 plus xxiv pages, thirty-five charts and 213 tables, over which I have burned much midnight electricity without finding any figures to fill out the series on compensation.

In column 5 the figure for deaths from tuberculosis in 1922 is obviously out of line. This appears to be because the only figures found were for deaths in Veterans' and Marine hospitals, while the figures for the years just before and after are for deaths in all hospitals. While the statistics are thus not quite complete, they do support the thesis that tuberculosis in recruits runs into big money when veterans call for compensation. Physicians who might be called on as examiners should have some conception of their financial responsibility to the government, and obviously the most efficacious means of examination should be adopted.

Figures have not been found as to the number of tuberculous veterans who were taking vocational training. The total figures were not subdivided into the three great classes of neuropsychiatric, general medical and surgical, and tuberculosis. One inherent difficulty with the scheme of vocational training was this: Except for statutory total disability ratings for amputations, blindness or other disabilities that did not confine the veteran to bed, as a rule only veterans were eligible who were less than totally disabled and who were therefore drawing less than the \$80 to \$100 a month, varying with dependents, which such a rating called for. Under section 2 the maintenance allowance averaged \$126 a month, and under conditions attained a maximum of \$170 (Annual Report, 1923, p. 391). The 1922 report says on page 283:

About 50 per cent of these beneficiaries know that if they apply themselves and complete their training their Government allowances will stop and they will receive less money as initial pay in their new vocations. It is not reasonable to expect all of the group to voluntarily apply themselves to reduce their incomes, especially when they can readily discover the indifferent employees and school officials who will condone their harmful tendencies.

With perhaps unconscious naïveté the statement is made on page 18 of the 1922 report:

Section 2 trainees receive maintenance allowance during the period of training, and during that time are discontinued from the compensation roll. When they have been rehabilitated they will be replaced upon the compensation roll.

Vocational training aimed to prepare veterans not only for trades but, if they were qualified for it, for professions. The annual report for 1923 states on page 40:

There are 968 trainees in medical schools, 1,176 in dental schools, and 520 students in pharmacy. In addition to this, there are 146 students in veterinary surgery, 99 in osteopathy, and 314 taking training in chiropractic.

Vocational training was discontinued with the end of the fiscal year 1928, and the total cost of it, stated on page 35 of the annual report for that year, was \$645,007,450.62. In the absence of statistics showing the classification of trainees by kind of disability, one can only estimate that, since the percentage of tuberculous among the total drawing compensation during the years when the training was in effect varied from 20.68 to 23.70, a reasonable and probably a low proportion to be charged to tuberculosis would be 20 per cent, or 129 million dollars.

METHODS USED DURING THE WORLD WAR

An inquiry as to whether tuberculosis could be more efficiently weeded out in a present day mobilization than it was in the World War necessitates an examination of the methods used for its detection in recruits in 1917 and 1918. The total armed forces of the United States during that war totaled 4,800,000,¹ of whom 4,000,000 were in the army. A study of the army procedure will therefore account for the greater part of the problem. The adviser of Surgeon General Gorgas on all matters pertaining to tuberculosis was the late Col. George E. Bushnell. That this study will lead to conclusions as to certain fundamentals that differ from the opinions held then by Colonel Bushnell should not be interpreted as evidence of either a motive or a desire to detract from the stature of that distinguished army surgeon. Much of the difference in question has been

1. Ayres, L. P.: *The War with Germany: A Statistical Summary*. Washington, D. C., Government Printing Office, 1919.

derived from a study of the very veterans on whom Colonel Bushnell and his personnel passed when the former were recruits, and Colonel Bushnell is not to be reproached for not having knowledge that came into existence only later, any more than the chief of the army air service in 1917 is to be reproached because more efficient planes are available now than then.

It was the consensus of experts in 1917 that adult exogenous infection with tuberculosis is rare, that infection in childhood is well nigh universal and that every infection confers an immunity to anything short of massive doses of bacilli in later life. By the same token, adult tuberculosis was held to result from a reactivation of the antecedent infection. As late as 1928 I was responsible for a brief opus espousing this thesis,² with a by-line to the Trudeau School of Tuberculosis at Saranac Lake, N. Y., where I was taught it in 1919. Colonel Bushnell was a vigorous adherent of this outlook³ and stated:⁴

In the opinion of the medical officers most conversant with the facts, the number of soldiers who had incurred manifest tuber-

be difficult to explain away: for example, the development of six cases in one college fraternity a year after one of its members was found to have a positive sputum, and the development of tuberculosis in a girl several years after her sorority room-mate was found to have tuberculosis. As far as army recruits go, the more efficient the weeding out process for active tuberculosis, the more the question of adult exogenous infection approaches the realm of academic interest only. The problem in hand is this: How can the recruit who already has active tuberculosis be recognized, that he may be rejected for the protection of himself and others?

Colonel Bushnell did a monumental piece of work in training a large number of highly competent physical diagnosticians, to whom he imparted the significance of the post-tussal moist rale and the technic of eliciting it. To a motion picture prepared under his direction, part of it using the principle of the animated cartoon and which I saw not in the army but at school in Saranac Lake, I owe the following indelible concept:

TABLE 1.—Cost of Compensation

Fiscal Year	Total Number Compensated	Vocational Trainees, Section 2	Service Origin Tuberculosis		Deaths from Tuberculosis in Fiscal Year	Compensation per Month, All Causes	Compensation per Month, Tuberculosis	
			Number	Per Cent			Total	Average
1939.....	342,072	55,634	16.27	1,947	\$13,659,562	\$2,963,637	\$53.36

† Death and disability claims paid to date. Later figures do not include compensation for deaths in service.
‡ Only figure available is for cases in hospitals, U. S. Public Health Service and private.

culous disease as the result of military service was to the number of those who had brought the disease with them into the Army approximately as 1 to 10. In reality it is probably considerably less than 1 to 10.

I am told by more than one recognized expert in tuberculosis that they do not look on adult exogenous exposure today with the degree of complacency that was the rule earlier. The importance of the topic to this study lies in the self-evident conclusion that, if a recruit with open tuberculosis is capable of setting up new lines of tuberculosis in his barrack-mates, an increase in the efficacy of the weeding out process will be of all the more importance in that it will not only take out the individual case but will eliminate others that would develop from the contact. Just to take one communication at random from the copious literature on adult exogenous infection, Diehl and Myers⁵ present evidence on tuberculosis in college students that would

Tuberculosis produces a sticky exudate in the smaller air passages; when they collapse, this exudate glues them together. When they reexpand they separate with a snapping sound, and this snapping sound is the moist rale. So much for the mechanics of the rale. Equally lucid is the presentation of how to elicit it: to get the walls to collapse so that they will stick together, it is necessary to exhaust as much of the contained air as possible. This is achieved by having the patient cough gently at the end of deep expiration. When he inhales after the cough, the air enters, the glued-together walls separate with a snap and the rale is heard in the inspiration that follows the cough that follows the expiration. It is as simple as that. The man who knew the substance of the present paragraph had gone a long way toward becoming a chest expert. (Compare Lawrason Brown: "The specialist has the patient cough, the general practitioner does not.")

We are now in a position to appreciate a situation which involved the draft boards and the chest experts. It should be remembered that in 1917 there were set up in every community draft boards which included local physicians who were supposed to reject draftees with disqualifying defects. The evil that men do lives after them. The good is oft interred with their bones.

4. Bushnell, G. E.: Tuberculosis: The Medical Department of the United States Army in the World War: Communicable and Other Diseases, Washington, D. C., Government Printing Office 9: 200 (chapter 3) 1928.
5. Diehl, H. S., and Myers, J. A.: Tuberculosis in College Students, Tr. Nat. Tuberculosis A., 1936, p. 163.

There is statistical evidence that a great many of the draft boards functioned honestly and intelligently. Their work does not come into the picture today as does that of certain others. To come to the point briefly: "Matson's remark with reference to Camp Lewis⁶ that the material was largely from the Southwest and contained enormous numbers of health seekers whom the boards of the first draft sent, thinking that change of climate might benefit the manifestly tuberculous, undoubtedly applies with even greater force to the command at Camp Kearny.⁷ . . . "In the reexamination of 19,827 men at this camp, 853 cases of tuberculosis were discovered, or 4.83 per cent." It is an astounding state of affairs to find evidence in the army's official publication, written by Colonel Bushnell, that, far from weeding out the manifestly tuberculous, some of the draft boards actually concentrated tuberculosis at some of the camps. It will be shocking when its full force sinks in, after figures are shown on what it costs to take a man with tuberculosis into the army.

The first thing that happened to these recruits after they learned to sing "You're in the army now" was to get an injection of typhoid vaccine, which in a great many cases resulted in a very sore arm. While in a state of body and mind scarcely less lamentable than that in a much earlier military venture described in Genesis 34:25, the recruits were formed in line and conducted past medical enlisted men who taught them to breathe in, breathe out, cough, breathe in, and those who exhibited persistent moist rales to the officers listening in on the last respiratory phase mentioned, with or without such other classic signs as narrowing of Krönig's isthmus, went no further in their military career. One might think that the men rejected were returned to their homes and that that was the end of the matter. The situation was very much otherwise. Many of those rejectees had not known until then that they had tuberculosis. By the simplest association of ideas, many of them believed that what made the arm sore was responsible for the tuberculosis. But whether they learned *de novo* that they had tuberculosis, with or without the belief that it was the "T. P. shot" that produced it, or whether they had come to the cantonment for the change of climate on the prescription of the draft board physician, every one of these rejectees was able to present evidence, acceptable under the law, that dictated the course of the War Risk Insurance rating doctors, of whom I was one, that their tuberculosis had been aggravated by their few days at camp, and they went on the payroll from that time on for the aggravation of the preexisting disease, just the same as if they had incurred it at camp. That the army chest experts got these men too late to prevent their drawing compensation for life, and their dependents after their death, was not the fault of the army chest experts. It was the fault of the draft board setup. It should not have happened in 1917, and it particularly should not happen in 1940, when the public debt is \$327 per capita compared with the 1917 level of \$28.⁸

THE COST OF TUBERCULOSIS

In addition to the compensation and the vocational training, there is a very large additional item to be reckoned in the cost of tuberculosis in the World War. That is the excess of insurance benefits over premiums paid in. Certain figures from the annual report of 1922

are of interest: approximately 4,500,000 persons applied for war risk insurance, or 94 per cent of the 4,800,000 comprising the total armed forces; 80 per cent of the applications were for \$10,000, and the average amount of term insurance applied for was \$8,756. "Over 75 per cent of the men who carried term insurance while in service never paid a premium after their discharge." "The average age of those in service during the war was under 24 years" (Annual Report, 1924 p. 456). The premium at age 25 was \$7.92 per thousand (p. 24).

The annual report for 1924, which was the last fiscal year in which there was a statutory service connection for all cases of tuberculosis, gives figures on pages 399 and 400 which are informative. As of June 30 that year 12,024 veterans had died of tuberculosis on whom there was in force a total of \$99,926,940 of insurance, and 3,833 veterans still living but rated as permanently and totally disabled from tuberculosis were drawing monthly against a total of \$33,043,915; an average policy in force on the deceased group of \$7,868 and for the living group of \$8,621. I have not found figures giving the exact amount of premium credit to be deducted from this total of \$132,970,855, but had premiums been paid monthly at the rate of \$7.92 per thousand annually from the date of the War Risk Insurance enabling act to the end of the fiscal year 1924, the total could not have exceeded $7\frac{1}{3}$ million dollars. To estimate the excess of benefits over premiums as 130 million dollars comes exceedingly close to the actual figure.

Since 25 per cent of the veterans never paid a premium after discharge, any tuberculosis developing after the fiscal year 1924, even though it might be rated as service connected for compensation, had under a 25 per cent chance at best of being covered by insurance in force. So, while there was doubtless a matter of a few million dollars of excess benefits over premiums involved in tuberculosis that developed after that time, it does not enter into an estimate of the insurance cost of tuberculosis that presumably was taken into the service.

There are now some figures to add up:

Pro rata share of tuberculosis in vocational training, 129 million dollars;

Insurance cost of tuberculosis, 130 million dollars;

Compensation cost of service connected tuberculosis to date, in round numbers, 600 million dollars;

Hospital care of service connected tuberculosis, 100 million dollars (table 6).

Total, 959 million dollars.

and the end is not yet. This figure does not include any pro rata share of a number of million dollars expended for hospital construction. Every month that goes by sees approximately three million dollars for compensation added to this bill, and it will take only about five more years to bring the cost of service connected World War tuberculosis to the figure of one billion dollars.

It becomes a nice problem in accounting to estimate, from the foregoing data, just how much it costs to take a man into the service when he has tuberculosis. Any attempt to draw an exact conclusion from the foregoing data would seem silly to me, because the calculations would involve so many factors that are still unknown; but one can form some estimate at least of the order of the figure, and I make it out somewhere around \$10,000 per man to date, certainly not less than \$7,500, a figure to which can be added at least \$50 a month for the rest of the man's life and compensation benefits for

6. Matson, R. C.: The Elimination of Tuberculosis from the Army, *Am. Rev. Tuberc.* 4: 398 (July) 1920.

7. Bushnell: *Tuberculosis*, p. 182.

8. Editorial, *New York Sun*, Aug. 7, 1940.

his dependents after his death. This should answer the question What price change of climate for a man with tuberculosis on the draft board doctor's prescription? It should be remembered that at Camp Kearny alone there were found 853 men with tuberculosis whom the draft boards should have turned back and could have turned back had the examiners known the mechanics and significance of the persistent moist rale and acted on it.

COMPARISON OF METHODS

We now have a background to prepare us for a study of the methods used in the examination of recruits in 1917, compared with the methods available today. Of the three available methods for the mass diagnosis of tuberculosis in the living, namely physical diagnosis, x-ray examination and the tuberculin test, what should be the role of each if the problem of 1917 should confront us again today? I do not propose to advocate the tuberculin test for the mass examination of recruits, which leaves the problem, so far as my own discussion of it is concerned, as to a study of the relative merits of x-ray examination compared with physical diagnosis; not that the x-rays are not a physical means of diagnosis, but using the term physical diagnosis in its time honored sense, implying that the examiner has nothing to aid his own five senses, and relying principally on three of those. This does not ignore the fact that the diagnostic finding *par excellence* is bacilli in the sputum, but for obvious reasons this is not applicable to large scale surveys without previous selection of material.

There is much material available for a study of the relative efficacy of radiography and physical diagnosis, based on the work of examiners who have applied both methods to large numbers. Before I go into these sources I will present some unpublished material put at my disposal by Dr. Lewis Gregory Cole, supplemented by certain follow-up data provided by the adjutant general's office and the research section of the Veterans' Administration. I quote Colonel Bushnell:⁹

Considerable pressure was exercised during the first months after the United States entered the war by a number of prominent physicians and radiologists to induce the Surgeon General to make the radiograph the decisive factor in the diagnosis of pulmonary tuberculosis. The claim was that the work could be done with great rapidity and accuracy, that the negatives were easily stored in a comparatively small space and would form a permanent and more or less infallible record which would not only be of great scientific value but would also decide better than the results of physical examination as to the necessity of rejection, 90 per cent approximately of the men being accepted on their radiographs without further examination of the lungs, leaving the remaining 10 per cent for further study. Even granting that all of the above claims were well founded, it was evident that the practical difficulties in the way of the adoption of this plan were insuperable. Not to mention the enormous cost of photographing the new army and the impossibility of obtaining a sufficient number of plates within a reasonable time, the lack of trained radiologists had to be considered.

The objections stated in the last sentence are not valid today. We have seen that the financial aspect of tuberculosis in the army is of such magnitude that if radiography can promise a substantial saving the cost of doing it fades into insignificance. As for the lack of trained radiologists in 1917, that was true enough; but today the American Board of Radiology lists more than 1,450 diplomates, not counting those limiting their practice to therapy. This does not include a large number of specialists in tuberculosis who have their own x-ray equipment and would be qualified to partake

in meeting an emergency such as the one under discussion. And as for the drawback in 1917 pertaining to a supply of plates (made of glass, most of it imported from Belgium), the magnitude of the x-ray film business today is such that it could meet any demand for films, however great.

To resume the quotation:

A subcommittee of the general medical board of the Council of National Defense undertook a test to determine practically the merits of the proposed scheme. All of the members of certain companies of the 69th New York Regiment, National Guard (later renumbered the 165th Regiment of United States Infantry) were photographed by the x-ray. Certain men diagnosed as tuberculous by this means were examined subsequently by an examining board composed of experts in physical diagnosis from New York City. For various reasons the total number of those who could be obtained for reexamination was only twenty-five. Of these twenty-one were found to have no abnormal physical signs, one had distinct signs of apical involvement with rales in both apices but gave no symptoms, and three had only slight or equivocal signs, of whom but one gave pulmonary symptoms. The last four men were rejected, one of them, however, not on account of physical findings, but because of suspicious history and radiograph. The board was disposed, as will be noted, to be most liberal in its concessions, but its findings can hardly be said to make out a good case for the method, which in this instance was put into effect by skilled radiologists.

It was Dr. Lewis Gregory Cole who put most of the pressure on the surgeon general aforementioned, and it was Dr. Cole who made this survey. There is a slight numerical discrepancy between the figures he gave me and the figures just quoted, in that Dr. Cole recommended the rejection of nineteen men all of whom showed in his opinion definite radiographic evidence of tuberculosis. One showed a cavity, three showed consolidation and the rest showed soft mottling. Not one of these nineteen showed any physical signs, and it is this lack of confirmation by the then supreme criterion that is responsible for the statement that the results could hardly be said to make out a good case for the method. I undertook to follow up the records of these nineteen men to see how many of them later drew compensation for tuberculosis. Of the nineteen, one was killed in action, which eliminated him as a possible claimant for disability as a veteran; of the other eighteen, three were discharged from the army on surgeon's certificate of disability for active tuberculosis before the calendar year 1917 was out and five others died of pulmonary tuberculosis at intervals up to 1938, all eight having been beneficiaries of compensation. No claims were found for the other ten, which may or may not mean that none of them received compensation because of tuberculosis. The possibility must be admitted that one or more of the ten could have filed a claim that was not found when the records were searched for the study. If the ten are left out of it entirely, there is still proof that eight out of the eighteen became heavy compensation liabilities.

X-RAY EXAMINATION VS. PHYSICAL DIAGNOSIS

Evidence bearing on the relative value of x-ray examination and physical diagnosis is available from the home office of the Metropolitan Life Insurance Company in New York. This office at the present time comprises 15,000 employees. The company provides care in its own sanatorium at Mount McGregor for any employees who come down with tuberculosis. For obvious reasons the company does not accept as employees persons with manifest tuberculosis at the time of application. Evidence of tuberculous infection is not cause for rejection,

9. Bushnell. Tuberculosis, p. 193.

but evidence of a parenchymatous lesion is, whether past or present. The company does not discriminate against applicants showing a healed primary complex or hilar calcification. In a recent communication Dr. H. H. Fellows, who initiated and supervises the procedure for caring for the employees, has studied a

* From 1926 through 1939 all applicants for employment at the home office received a routine roentgenogram following physical and fluoroscopic examination; therefore, from this date on, the number of applicant examinations is the number of individuals roentgenographed.

large number of employees with and without signs of a healed primary complex and has found the tendency to break down with tuberculosis no greater in the ones who show it.¹⁰ The examination which the applicant is put through is to discover an active parenchymatous lesion or an old one which carries a hazard of becoming reactivated. In my opinion this is identical with the problem that a mobilization would bring. In 1917 the desideratum was to keep out active tuberculosis, but men with obsolete lesions were accepted. The subject is discussed at length in the chapter on tuberculosis by Colonel Bushnell, previously cited. Since the previous mobilization came nowhere near exhausting the supply of man power, the conservation of men to the service with obsolete lesions seems to me today much less important than excluding them for fear that a reactivation would make them compensation liabilities, viewing the problem from the fiscal angle, while it is certainly undesirable to subject a man to the risk of reactivation, viewing it from the medical angle.

But whether the problem in a mobilization today would be to exclude all tuberculosis, in conformity with the procedure of the life insurance company cited, or to exclude only active tuberculosis, the company has statistics that are of intense interest in the present problem. It has data over a period of years on tuberculosis in applicants and on the detection of active tuberculosis in employees. A leaflet published by the company in 1935¹¹ presents the figures through 1934. An article by Dr. Ada Chree Reid¹² in process of publication presents the figures from 1928 through 1939 on tuberculosis in applicants, and a second communication¹³ in process of preparation presents them from 1930 through 1939 on tuberculosis in employees. The company has definite data on the relative value of physi-

cal examination and x-ray examination. Dr. Reid gave me the opportunity to use her figures.

She concludes:¹² "In detecting pulmonary tuberculosis in apparently healthy groups, history and physical examination of the chest are of limited value. Routine x-ray films are the most reliable procedure, but an expensive one."

I have already given some notion of the cost of taking into the army a man who has tuberculosis and have shown that the cost of an improved method of diagnosis would amount to very little in comparison with the saving in the long run.

In the twelve years 1928-1939, 25,171 applicants were examined. The ratio of females to males was 70.4 to 29.6. They were predominantly young, 85.3 per cent being under 30 years. The term "clinically significant" will be used directly; therefore it will be defined:

Includes all cases in which the radiographic shadow indicates a lesion typical of a reinfection form of the disease varying from those obviously active, with associated constitutional symptoms and physical findings, to those without associated findings, but in which the stability of the lesion cannot be determined without periodic supervision.¹⁴

The term "pulmonary tuberculosis" means a parenchymatous lesion; a healed primary complex and/or calcified hilus nodes are not included in this category.

The incidence of tuberculosis in this group of applicants is of sufficient interest in the present study to justify reproducing the table (table 2).

It will be seen from table 2 that when fluoroscopy was introduced as a routine in 1927 the number of applicants examined was at a level so high that the expense of roentgenography would have been formidable. In 1935 (August 1) roentgenography was introduced, one reason being that it was desired to check on the accuracy of fluoroscopy. Roentgenography of the chest of all applicants has been maintained as a routine since that time, and one advantage is, in addition to its being more accurate than fluoroscopy, that there is a film on record for future reference. In 1937 Dr. Fellows reported¹⁵ on 2,603 examinations on applicants for employment, applicants for insurance and others, the examination embodying both fluoroscopy and roentgenography. His observations are given in table 3.

Of the fourteen cases constituting the 13 per cent missed by fluoroscopy, "five were latent or clinically insignificant, while nine were considered clinically active. These nine were classified as minimal and examination of the chest failed to reveal any physical findings."

TABLE 3.—Cases of Tuberculosis Discovered by Roentgenography and by Fluoroscopy

Number examined	2,603
Tuberculosis discovered by roentgenography.....	169
Tuberculosis discovered by fluoroscopy.....	85
Tuberculosis missed by fluoroscopy.....	14
Percentage of error.....	13

Dr. Reid¹² presents a table (table 4), reproduced here, which covers the total of the examinations listed from 1928 through 1939 totaling 25,171 examinations and 311 cases of tuberculosis, 200 of them clinically significant. The size of this group and the unquestioned competence of the examiners make the figures of extreme value to an appraisal of the accuracy of

physical diagnosis compared with x-ray diagnosis. It must be kept in mind that, since roentgenography did not become routine until past the middle of 1935 (though it was used sporadically before that time), the percentages derived from the totals for the twelve years assign to roentgenography an importance considerably below its actual value. Only the figures from 1936 on afford an estimate of the comparative value of roentgenography and other methods of diagnosis including fluoroscopy. For this reason, two lines have been added to the table constituting a segregation of the figures for 1936-1939. The column headed "unknown" refers to cases in which the record was incomplete as to the method used to establish the diagnosis.

It is self evident that all cases presented a positive roentgenogram but the figures in the column headed "Roentgenogram" are smaller than the number of cases. This is because the diagnosis was credited to the first means which made it, reading the column headings from left to right. If a case showed physical signs, the diagnosis was credited to physical signs and not to fluoros-

the applicants' group introduces some element of personal equation; in the employees' group this is eliminated, and the figures stand as the results found by a competent examiner on subjects already shown by the roentgenogram to be tuberculous. Even under these favorable auspices for positive results competent physicians found rates in only thirty-four of 254 cases and no rates in 208.

This is not a palatable conclusion for older clinicians who pride themselves on their ear for signs, and the immediate reaction that can be anticipated is that the competence of the physical examiner(s) will come into question. Dr. Reid tells me that even the check-up examinations are not done under entirely ideal conditions of quiet but that she feels that the conditions under which the work is done are at least as favorable as would attend the mass examination of recruits by an army chest board. Furthermore, the record should show that more than 90 per cent of the tuberculous employees accept sanatorium treatment at Mount McGregor, where the resident staff includes one man

* In one case a roentgenogram was ordered because of poor general appearance; no chest signs were present.

copy; if fluoroscopy was the first means to establish the diagnosis, the diagnosis was credited to that and not to roentgenography. Obviously cases are not subjected to a hard and fast diagnosis on family history, but in cases in which the family history was sufficiently strong to lead to great suspicion, and that suspicion was confirmed by other means, the diagnosis was credited to family history. An employee coming down with a pulmonary hemorrhage would be apt to show physical signs, but the diagnosis is credited to symptoms. Therefore it would be an injustice to the procedure of physical diagnosis to estimate its efficacy by the percentage of diagnoses with which it is credited in table 4.

Fortunately the significant data on all the cases diagnosed in applicants and employees are on cards in Dr. Reid's possession, and she went over 624 cards to give me the figures in table 5.

Owing to incomplete records on a very few cards, the books do not quite balance as to totals for physical signs and for fluoroscopy; but the error is not statistically significant.

The great majority of the applicants diagnosed as tuberculous and all of the employees so diagnosed were referred to Dr. Reid for further study. "Positive on reexamination" refers to the specialist's check-up examination. That Dr. Reid did not examine every one of

who to my personal knowledge was on the resident staff at Trudeau too long not to know physical signs when they are present and whose skill in physical diagnosis will be attested by any one who ever attended the Trudeau School of Tuberculosis in his time. I refer to Dr. G. S. Pesquera. There is no significant disagreement on physical signs between the staff at Mount McGregor and the home office staff that refers the patients; just to show that the home office staff is not diagnosing imaginary tuberculosis, one patient out of three has a positive sputum, physical signs or no physical signs.¹¹

It is not expected, in the event that an army should be raised today, that it would be equipped in matériel and training with nothing later than 1917. By the same token "the only trustworthy sign of activity of apical tuberculosis is the presence of persistent moist rales,"¹⁰ which was the last word, so far as the army was concerned in 1917, is shown in the light of present day knowledge to be worth only about 12.5 per cent. There is every reason to believe that for all the skill of the army examiners, and they included a large number of specialists from Lawrason Brown down, who were accepted for special service notwithstanding that they

16. Bushnell: Tuberculosis, p. 175.

were tuberculous themselves, only about one eighth of the actually existent clinically significant tuberculosis was detected because of the limitations of the method. In 1917 it was not common to take roentgenograms of chests unless they showed physical signs. The seven-fold excess of roentgenographically demonstrable tuberculosis over stethoscopically demonstrable tuberculosis became common medical knowledge only some years later.

RADIOGRAPHY THE CRITERION

This paper has been an utter failure if it has not established that radiography should be the criterion in weeding out tuberculosis in the event of mobilization today and that the cost of the procedure is negligible in comparison with the saving. The question then arises How should the radiography be done? The omission of fluoroscopy is deliberate. Fluoroscopy gives no permanent record, it is highly subjective and it introduces the personal equation, and I offer no rebuttal to the devastating attack on it made by Matson¹⁷ in respect to its value in detecting tuberculosis in recruits. Crediting the five questionable cases as hits, the Metropolitan's statistics just quoted credit the fluoroscope with 210 positive results and 37 negative, an error of 15 per cent, scarcely negating Fellows' earlier claim on material in the same series of an error of 13 per cent. This is a much smaller percentage of error than I find quoted by any other workers in tuberculosis. Much more typical, in my own belief, are the results of Boynton, Diehl and Shepard:¹⁸ In 126 cases of the adult type of tuberculosis among Minnesota University students, fluoroscopy suggested pathologic changes in 56 per cent of the fibrotic cases, 34 per cent of the incipient, 57 per cent of the moderately advanced and in all of the far advanced. This does not imply that, to transfer the procedure to mobilization, fluoroscopy would do as well as 50 per cent accurate; because in 5,158 students sampled at random over a period of five years, "in 13.3 per cent the fluoroscopic findings were suggestive of pulmonary pathology; in 5.3 per cent the x-ray of the chest was positive." But this 5.3 per cent does not mean the adult type of tuberculosis, because the incidence of that for the whole student body was only 0.18 per cent. I will add my voice to Matson's that to set up fluoroscopy as the criterion at a time of mobilization would be a grave error. However, I dissent from his deprecation of "roentgenology" when he uses the term to designate fluoroscopy. Radiography is something entirely different. At the Metropolitan Life Insurance Company, where an annual examination of the employees would require 15,000 roentgenograms if roentgenography were made a routine, fluoroscopy in the hands of a highly alert personnel serves the purpose as an alternative to a prohibitively expensive routine of roentgenography; but even the Metropolitan is continuing today its routine roentgenograms, adopted in 1936, of the chest of every applicant, to be filed for future reference, and it uses roentgenography freely on employees whenever needed.

To return to the question of how to do the radiography, there are all kinds of x-ray machines, from portables to three phase installations costing \$6,000, with tubes varying from the portable tube at something like \$100 to the rotating anode tube at something like \$700. There are films, with and without intensifying

screens, and there is paper; of late there is photography of the fluoroscopic screen, further subdivided into 4 by 5 inch photography and 35 mm. photography. Every permutation and combination of equipment has its articulate proponents and its commercial representatives. During my vacation in the past summer I was shown an installation in a large university which had come in for considerable criticism by a reputable institute that enjoys a reputation as a consultant on x-ray installations. The machine used only one rectifying tube, which was reported as not the ideal equipment for chest work; and yet this modest outfit, which the institute quite properly found far behind the ideal, was producing technically excellent roentgenograms on which incipient tuberculosis was being diagnosed long in advance of physical signs. Theoretically, the best chest radiography is that done with the shortest exposure, with the smallest focal spot, at the maximum feasible tube-film distance by the most competent worker. The last specification, in my opinion outweighs all the others. The short exposure requires power; the smallest focal spot requires a rotating anode,

and so on. A communication by Pesquera and Sampson¹⁹ presents a curve showing expenditure of money plotted against sharpness of radiographic detail, and it is of more than passing interest that it is the same old exponential curve, the curve of the law of diminishing returns, that governs the whole gamut of vital processes. This curve is true, all other things being equal; but as between, let us say, Sampson with a portable machine and Joe Doakes with a \$6,000 three phase machine, I will take the work of Sampson every time.

The paper roentgenogram vs. the celluloid film is a leading matter of controversy today, the radiologists as a whole having very little use for the paper while the tuberculosis workers are enthusiastic over it because it comes in rolls of 100 exposures, which can be converted into roentgenograms as fast as the personnel can affix the roentgenographed-on labels and conduct the subjects to the machine. The roll is sent back to the factory for processing and a few days later is returned to the survey staff for reading. The cost per unit of sensitive surface is about half that of the film; the handling is much less expensive because of the application of mass production. Yet I have not the slightest

doubt that, were the manufacturers of celluloid film to make that material available in similar form, the most enthusiastic devotees of the paper would gladly switch to the celluloid. There is no question that the roll of 100 exposures lends itself to rapid surveys much better than the single film, and between washing 100 14 by 17 films in the average darkroom and having the 100 on a roll processed at the factory, there is no question either. As I visualize the problem of a sudden demand for say a million chest roentgenograms, it is my own notion, not based on anything official from the army, that the army has a pretty good idea what the radiographic resources of the country are and where they are; and it would require the whole-hearted cooperation of every facility that can produce an acceptable roentgenogram to execute the job, without any controversy over paper vs. films. I am not a devotee of paper; but I should vastly prefer paper roentgenograms to no

TABLE 6.—Cost of Hospital Care of Service Connected Tuberculosis

Column 1 of this table is from a personal communication from the chief of statistics of the Veterans Administration dated Sept. 27, 1940.

Columns 2 and 3 are from table II of the Annual Report of the Administrator of Veterans' Affairs, 1939.

Column 4 is derived by multiplying column 1 by column 3.

* Indicates estimate by extrapolation in the absence of available figures.

roentgenograms and I should prefer celluloid to paper were I given the choice.

As to photography of the fluoroscopic screen, I have very serious doubts whether it is as good as 90 per cent efficient compared with the standard celluloid roentgenogram, and a 10 per cent shortage in diagnosis would cost a great deal of money in compensation later, as can be seen by referring back to the compensation statistics. This method, known as fluorography, is limited at present to institutions that on occasion could produce probably an equal number of roentgenograms of full size were expense not the consideration. The difference in cost between full sized roentgenograms and 35 mm. miniatures would be saved many times over and over on a differential of diagnostic accuracy of only 10 per cent. Fluorography is today a highly promising method, but for it to compete with celluloid roentgenograms as to accuracy awaits, in my opinion, a fluoroscopic screen free from grain, and to date freedom from grain entails sacrifice in speed.

Readers of Tolstoy will recall a situation in Anna Karenina in which Kitty, pining for unrequited love,

went into a decline. A big specialist was called in who delivered himself as follows: "The commencement of the tuberculous process we are not, as you are aware, able to define; till there are cavities, there is nothing definite. But we may suspect it. And there are indications: malnutrition, nervous excitability, and so on."

This was written in the sixties, and yet in 1917 Dr. Lewis Gregory Cole demonstrated a pulmonary cavity in a member of the New York National Guard who showed no physical signs and was taken into the army, only to be discharged on S. C. D. for tuberculosis before the calendar year 1917 was out and went on the compensation roll at once as a total disability.

The point might be raised that the death rate from tuberculosis was 124.6 per hundred thousand of population in 1917 and only 49 in 1937. This comes far from proving that the incidence of clinically significant tuberculosis in the population has undergone a proportionate reduction. In 1928, when the Metropolitan Life's home office statistics begin, the death rate was 70. The incidence of tuberculosis in its applicants has remained extraordinarily uniform over this period; certainly it has not shown the least tendency to parallel the death rate trend. The only approach to a nation wide survey of the incidence of tuberculosis was the sampling involved in the World War draft, and that was based on physical diagnosis. A radiographic survey today would, judging from the Metropolitan's figures, show approximately eight times as much, given an identical incidence. To reproduce the procedure of physical diagnosis in recruits by the same method as was used in 1917 would give statistics of tremendous value as to the incidence of tuberculosis now as compared with then; but, in the light of the material just examined, that would be its principal value. To use the physical examination as the criterion would be to take into the army a vastly augmented amount of diagnosable tuberculosis, and that is extremely undesirable for three principal reasons: the tendency of the strenuous exertion to activate latent tuberculosis, which is bad for the individual, the infection of adults in close contact (a conception not endorsed in 1917), which is bad for the community, and the excess of compensation resulting, which is bad for the taxpayer.

I regret that it has not been feasible to go thoroughly into the literature. However, to do so would be to postpone publication of this communication until a time possibly less opportune than the present.

SUMMARY AND CONCLUSIONS

1. Tuberculosis during and after the World War has cost approximately \$960,000,000 to date in compensation, vocational training, insurance and hospitalization.

2. Physical diagnosis, which was the criterion of fitness for the World War, is shown by experience, much of which has accumulated since that time, to be much less reliable than radiography in situations analogous to the examination of recruits.

3. A huge amount of compensation has been paid out to men manifestly tuberculous at the time they were sent to camp who should have been rejected by the local draft boards but were not.

4. A normal chest roentgenogram should be the criterion of acceptance in a future mobilization, including the proposed draft for training, and it should be made and reported before the recruit has spent a night away from his own roof to obviate a repetition of the claims for aggravation of preexisting tuberculosis which occurred during and after the World War.

115 East Sixty-First Street.

MOBILE HOSPITAL FOR THE NAVY

The U. S. Navy will ship next month to Guantanamo, Cuba, a new 500 bed mobile hospital which will be rushed to any outpost in the western hemisphere where American fighting forces may need hospital care. Packed in crates, the hospital measures 112,000 cubic feet and it occupies all the space on a 500 foot pier in the North River, New York. In the Brooklyn Navy Yard a freighter is being overhauled to transport the hospital. Thirty medical officers and 300 enlisted men of the navy will staff the hospital. Between its arrival in Guantanamo and Jan. 1, 1941, the staff will be given practice in unpacking and setting the hospital up completely and tearing it down for repacking. The new unit is part of the medical side of the national defense program and will be moved to outposts in South, Central and North America as the need arises.

ADVISORY COMMITTEE ON PREVENTION OF BLINDNESS

The National Society for the Prevention of Blindness has appointed an industrial advisory committee to deal with the increase in industrial eye diseases and accidents to the eyes which is expected to result from the national defense program. Industry has made progress in the campaign to protect the sight of workmen, but new processes have created additional hazards. The national defense program, necessitating the employment of large numbers of men in new jobs, working in strange surroundings, makes for an inevitable increase in the danger of accidents, it was stated. Dr. Leonard Greenburg, executive director of the division of industrial hygiene, New York State Department of Labor, will head the committee, which includes the following members:

Lyman A. Bliss, Linde Air Products Company, New York.
Roy Bonsib, chief safety inspector, Standard Oil Company of New Jersey, New York.
Dr. Morris Davidson, ophthalmologist, New York State Department of Labor, New York.
Edward R. Granniss, director, industrial engineering division, National Conservation Bureau, New York.
Harry Guilbert, director, bureau of safety and compensation, The Pullman Company, Chicago.
Charles E. Hill, general safety agent, New York Central Lines, New York.
George E. Sanford, General Electric Company, Schenectady, N. Y.
Dr. Donald M. Shafer, consultant, committee on healthful working conditions, National Association of Manufacturers, New York.
Leo D. Woedtko, Fred T. Ley & Company, Springfield, Mass.
V. A. Zimmer, director, division of labor standards, U. S. Department of Labor, Washington, D. C.

MEDICAL COMMITTEE FOR AID TO BRITAIN

A medical subcommittee of the Committee to Defend America by Aiding the Allies, of which William Allen White, editor of the Emporia (Kan.) *Gazette*, is chairman has recently been formed. The subcommittee urges physicians to enroll in local branches of the main committee, to send letters and telegrams to congressmen and presidential candidates stressing the need for all possible aid to Britain and to send contributions to the national committee. Members of the subcommittee are

Drs. Emile Holman, Eugene S. Kilgore and Ray Lyman Wilbur, San Francisco; Roger I. Lee, Boston; Warfield T. Longcope, Baltimore; John H. Musser, New Orleans, and Dallas B. Phemister, Chicago.

CALIFORNIA UNIVERSITY APPOINTS MEDICAL DEFENSE COMMITTEE

A committee of physicians and dentists to study ways and means by which the University of California Medical Center can contribute to national defense preparations has been appointed by President Robert Gordon Sproul. Dr. Howard C. Naffziger, professor of surgery, has been named chairman, and other members include Drs. Robert B. Aird, Leroy H. Briggs, Charles L. Connor, Leon Goldman, William J. Kerr, Karl F. Meyer, W. C. Fleming, D.D.S., dean of the college of dentistry, and Carl L. A. Schmidt, Ph.D., dean of the college of pharmacy. The committee will arrange to fill teaching vacancies which may occur when members of the faculty holding national guard or army and navy reserve commissions are called to active duty.

HOSPITALS OFFER USE OF CLINIC FACILITIES TO DRAFT BOARDS

The president of the Greater New York Hospital Association announces that fifty New York hospitals have offered the free use of their clinics and other facilities to local draft boards for the physical examination of conscription men. Physicians and other necessary personnel will be assigned by each local draft board. The physical examinations will be made in the evening. The following hospitals will cooperate with the local draft boards:

In Manhattan:	Swedish
Beckman Street	Norwegian Lutheran
Memorial	Deaconesses' Home
New York Polyclinic	St. John's
Medical School	St. Catherine's
Lenox Hill	Holy Family
Joint Diseases	Caledonia
St. Elizabeth's	Israel Zion
St. Vincent's	Beth-El
Sydenham	Methodist
New York Post-Graduate	Wyckoff Heights
Beth David	In Queens:
St. Clare's	St. John's
Manhattan Eye, Ear and Throat	Long Island City
Roosevelt	Jamaica
Lutheran	Rockaway Beach
Columbus	Flushing
New York Orthopedic Dispensary	Mary Immaculate
New York Infirmary for Women and Children	In Staten Island:
Beth Israel	St. Vincent's
French	Staten Island
In the Bronx	In Mineola:
Montefiore	Nassau
St. Francis	In Bay Shore:
Bronx	Southside
In Brooklyn:	In Hempstead
Long Island College	Mercy
Carson S. Peck Memorial	In Glen Cove:
Bushwick	North Country Community
Unity	In Huntington:
Brooklyn	Huntington
Prospect Heights	In White Plains:
	White Plains Hospital

17. Information About Syphilis.

An exhibit consisting of two transparency cases showing various syphilitic lesions; a large exposition microscope showing *Spirochaeta pallida*; an exposition file containing brief paragraphs on the subject of syphilis together with various charts and posters.

Space required, an area 10 feet wide by 6 feet deep; no background necessary.

Electrical connections, three outlets for lamps, requiring about 600 watts.

Shipping weight, 332 pounds.

21. Heart Disease.

An exhibit consisting of panels showing the normal heart, with transparencies showing diseased hearts; an exposition file giving information about heart disease.

Space required, an area 10 feet wide by 6 feet deep; no background necessary; small table for exposition file.

Electrical connections, one outlet for lights in transparency case using 240 watts.

Shipping weight, 435 pounds.

24. Prevention of Eye Injuries.

An exhibit used in conjunction with the Section on Ophthalmology of the American Medical Association, consisting of miscellaneous posters on panels ready to set up. The panels are accompanied by a transparency case showing transparencies of various eye injuries.

Space required, an area 10 feet wide by 6 feet deep; no background necessary.

Electrical connections, three outlets, with a total of about 400 watts.

Shipping weight, 240 pounds.

25. Prevention of Burns.

An exhibit used in conjunction with the Milwaukee Children's Hospital, consisting of miscellaneous posters on panels ready to set up and accompanied by a transparency case showing various injuries caused by burns. Where suitable arrangements can be made, a motion picture film on burns can be used with the exhibit. This will not be sent unless specifically requested. Motion picture, 16 mm., one reel, silent.

Space required, an area 10 feet wide by 6 feet deep; no background necessary.

Electrical connections, one outlet for lamps in transparency case using 200 watts.

Shipping weight, 240 pounds.

31. Information About Hospitals.

An exhibit from the Council on Medical Education and Hospitals consisting of a mechanical model of a hospital entrance with doors opening and shutting every three and a quarter seconds to indicate how often a patient enters a hospital in the United States; shadow boxes and miscellaneous charts.

Space required, a booth 10 feet wide by 6 feet deep with walls on which charts may be fastened.

Electrical connections, one outlet for small universal motor.

Shipping weight, about 300 pounds according to material selected.

34. Tularemia (spread and control).

An exhibit made in conjunction with Miami Valley Hospital, Dayton, Ohio, and U. S. Public Health Service, Washington, D. C., consisting of transparencies showing clinical cases of tularemia and posters on panels showing the prevalence, animal hosts, insect vectors and what to do to prevent infection. An exposition "microscope" shows the tularemic organism.

Space required, an area 10 feet wide by 6 feet deep; no background necessary.

Electrical connections, two outlets for lamps in transparency case and exposition "microscope" using 255 watts.

Shipping weight, 297 pounds.

42. "Patent Medicine" Testimonials.

An exhibit from the Bureau of Investigation consisting of posters showing testimonials for "patent medicines" with the death notice of the person in the same copy of the newspaper, or the death certificate dated some weeks or months previously. Two visitor participation units, one with a transparent mirror showing appropriate cartoon and one with questions and answers.

Space required, a booth with back wall 10 feet wide and side walls 6 feet deep for twelve posters each 22 by 28 inches; two small tables for transparent mirror and question and answer device.

Electrical connections, two outlets alternating current, using about 150 watts.

Shipping weight, 275 pounds.

44. Cancer Death Certificates.

An exhibit from the Bureau of Investigation in conjunction with the Texas State Board of Medical Examiners, presenting some two hundred cancer death certificates from an advertising "cancer" hospital.

Space required, an area 10 feet wide by 6 feet deep; no background necessary.

Electrical connections, none.

Shipping weight, 253 pounds.

46. Food Fads.

An exhibit from the Bureau of Investigation consisting of a mechanical attention arrester, two sets of transparencies showing persons whose diet requires special attention and persons whose diet should have been more carefully regulated; six posters each 22 by 38 inches dealing with some of the popular, but foolish, food fads; an exposition file with additional information.

Space required, a booth with back wall 10 feet wide and side walls each 6 feet deep; three small tables for transparencies and exposition file.

Electrical connections, three outlets for transparency cases and small universal motor totaling about 600 watts.

Shipping weight, 389 pounds.

55. Posture.

An exhibit from the Council on Physical Therapy consisting of a manikin for visitor participation showing correct and incorrect posture; transparencies showing reasons for good posture and panels with posters showing the relation of sitting and posture, the feet and posture, the causes of poor posture and recommendations for good posture. An exposition file gives additional information.

Space required, an area 10 feet wide by 6 feet deep; no background necessary; two small tables, one for manikin and one for exposition file.

Electrical connections, three outlets for lamps in cases using a total of 440 watts.

Shipping weight, 368 pounds.

61. Medical Economics.

An exhibit from the Bureau of Medical Economics consisting of miscellaneous charts; a rack for literature showing the publications of the Bureau, two exposition files containing various items of information concerning medical economics, and an automatic bar chart showing physicians in various countries.

Space required, a booth with back wall 10 feet wide and side walls each 6 feet wide for posters; a table 10 feet long.

Electrical connections, one outlet using about 200 watts.

Shipping weight, 400 pounds.

91. Hygeia in School, Home and Library.

An exhibit presented in conjunction with *Hygeia*, the Health Magazine, consisting of five dioramas showing the use of *Hygeia* in school, home and library.

Space required, an area 10 feet wide by 3 feet deep; table 10 feet long on which to place models; no background necessary.

Electrical connections, five outlets, requiring a total of 300 watts.

Shipping weight, 260 pounds.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION AND PUBLIC HEALTH.)

INDIANA

State Medical Meeting at French Lick.—The ninety-first annual session of the Indiana State Medical Association will be held at the French Lick Springs Hotel, French Lick, October 29-31, under the presidency of Dr. Karl R. Ruddell, Indianapolis. Included among the guest speakers will be:

- Dr. Roy Wesley Scott, Cleveland, Clinical Aspects of Arteriosclerosis.
- Dr. Charles A. Flood, New York, Prognosis and Treatment in Peptic Ulcer.
- Dr. Norvelle Chappell Lamar, New York, Common Physical Disorders of Childhood.
- Lieut.-Col. Robinson Hitchcock, on the staff of the adjutant general's office, state of Indiana, The Physician's Place in the Preparedness Program.
- Dr. Edmund L. Keeney, Baltimore, The Theory and Practice of Therapeutics in Allergy.
- Dr. Austin H. Wood, Baltimore, Clinical Urology.
- Dr. Ralph R. Mellon, Pittsburgh, Sulfathiazole, the Most Complete Sulfonamide Compound: Its Mode of Action.
- Dr. Emery A. Rovenstine, New York, Circulatory Disturbances During Anesthesia.
- Dr. Joseph M. Hayman Jr., Cleveland, Diagnosis and Treatment of Acute Nephritis.
- Dr. Irvin Abell, Louisville, Ky., Diagnostic Significance of Pain in the Abdomen.
- Dr. Fred W. Rankin, Lexington, Ky. (subject not announced).
- Dr. Nicholson J. Eastman, Baltimore, Indications for Cesarean Section.
- Dr. John Stanley Coulter, Chicago, Physical Agents in the Treatment of Fractures.

The annual banquet will be Wednesday evening with Dr. Frank H. Lahey, Boston, President-Elect, American Medical Association, and Mr. Walter McCarty, Indianapolis, managing editor, *Indianapolis News*, as the speakers. The latter's subject will be "Journalistic Obstetrics." The Indiana Association of Pathologists will meet Wednesday noon, October 30. Entertainment this year will include a trap and skeet shoot, Tuesday afternoon.

IOWA

Society News.—Dr. Howard C. Naffziger, San Francisco, discussed "Muscle Changes Associated with Thyroid Disease" before the Linn County Medical Society, October 10, in Cedar Rapids. Dr. Percy S. Pelouze, Philadelphia, discussed "Present Views on Gonorrhea and Its Treatment" before the meeting of the society, September 10.—Dr. Raymond J. Jackman, Rochester, Minn., addressed the Bremer County Medical Society and the staff of Mercy Hospital in Waverly, September 23, on "Anorectal Diseases: Diagnosis and Treatment."—The Cerro Gordo County Medical Society was addressed in Mason City, September 24, by Dr. Hugh R. Butt, Rochester, Minn., on "Recent Advances in Vitamin Therapy."—Dr. Abraham G. Fleischman, Des Moines, discussed "Clinical Aspects of Calculus Disease with Reference to the Kidney and Ureter" before the Greene County Medical Society, September 12, and Dr. Earl D. McClean, Des Moines, discussed the problems of the state society in completing the survey on medical preparedness.—Dr. Victor B. Buhler, Kansas City, Mo., gave a lecture and demonstration of laboratory procedures, assisted by Dorothy Dixon, M.T., Kansas City, before the Ninth Council District Medical Society, September 10. They demonstrated the micropothrombin test, pneumococcus typing by mouse injection, Aschheim-Zondek test by rabbit injection, injection of the guinea pig for tuberculosis and blood cultures. Physicians were present from Lucas, Wayne, Marion, Monroe, Warren and Appanoose counties.

KANSAS

Prize Essay Award.—The Sedgwick County Medical Society has approved a plan to award to a member of the society a cash prize of \$50 and a plaque for writing the best scientific paper of the year. The first award will be made in 1941. Competition is open to all members of the society and the papers are to deal with original work accomplished while the author is a member of the society. The essays must be in the hands of the program and postgraduate study committee not later than Oct. 1, 1941. Judging of the papers will be done by three members of the University of Kansas Medical School,

Drs. Ferdinand C. Helwig, Edward H. Hashinger and Thomas G. Orr, Kansas City, Mo. The papers, when presented to the judges, will be identified by number only. The winning essay is to be read before the first December meeting of the society and will be published as the Sedgwick County Medical Society Prize Essay.

MASSACHUSETTS

Mental Hygiene Meeting.—The annual meeting of the Massachusetts Society for Mental Hygiene will be held at the Twentieth Century Club, Boston, November 21. Dr. Arnold L. Gesell, New Haven, Conn., will give an address entitled "The First Five Years of Life."

New England Postgraduate Assembly.—The New England Postgraduate Assembly, sponsored by the state medical societies of Massachusetts, New Hampshire, Rhode Island, Maine and Vermont, will be held, November 13-14, in the Sanders Theatre, Harvard University, Cambridge. The speakers will be:

- Dr. Robert F. Loeb, New York, The Practitioner and the Problems of Diabetes.
- Dr. Russell L. Haden, Cleveland, Factors in the Production of Anemia.
- Dr. Sumner L. S. Koch, Chicago, Treatment of Injuries of the Hand.
- Dr. Henry W. Cave, New York, The Medical and Surgical Management of Diverticulitis of the Colon.
- Dr. Thomas Grier Miller, Philadelphia, The Causes of Indigestion and Their Recognition.
- Dr. Oliver S. Ormsby, Chicago, Fungous Infections of the Skin.
- Dr. Percy S. Pelouze, Philadelphia, The Urinary Bladder in Health and Disease.
- Dr. Fred L. Adair, Chicago, Management of Preeclampsia in Private Patients.
- Dr. Ralph M. Waters, Madison, Wis., Treatment of Respiratory Depression.
- Dr. Tracy J. Putnam, New York, Examination of the Nervous System.

At the dinner, Wednesday evening, with Dr. Reginald Fitz, Boston, as toastmaster, Dr. Harrison S. Martland, Newark, N. J., will speak on "Dr. Watson and Mr. Sherlock Holmes."

MICHIGAN

Society News.—Dr. Nathan B. Van Etten, New York, lectured before the Wayne County Medical Society, Detroit, October 7; his subject was "Medical Horizons."—Dr. Jean P. Pratt, Detroit, discussed "Pelvic Lesions Simulating Appendicitis" before the Calhoun County Medical Society in Battle Creek, September 3.—The Michigan Society for Crippled Children will hold its nineteenth annual convention in Kalamazoo, November 14-16. Additional information may be obtained from the Executive Secretary, 548 Buhl Building, Detroit.—Dr. Richard McKean, Detroit, discussed "Common Cardiac Disorders" before the Washtenaw County Medical Society in Ann Arbor, September 10.

Venereal Disease Clinic.—The second venereal disease clinic day of the Ingham County Medical Society will be held at the Hotel Olds, Lansing, November 7. The theme of this year's meeting will be gonorrhea, and speakers will include:

- Dr. Raymond A. Vonderlehr, U. S. Public Health Service, Washington, D. C., Morbidity and Mortality Rates in Gonorrhea, Immediate and Remote.
- Dr. Adolph Jacoby, New York, Diagnosis and Criterion of Cure.
- Dr. Percy S. Pelouze, Philadelphia, Treatment of Gonorrhea in the Male.
- Dr. Vincil Rogers Deakin, St. Louis, Treatment of Gonorrhea in the Female.

Dr. Vonderlehr will address a public meeting in the evening on "Present Day Venereal Disease Control."

MINNESOTA

Mr. Awe Fined.—William F. Awe, aged 53, who gave Denver as his home address, was sentenced, September 21, by Judge Vernon Gates of the district court at Rochester to pay a fine of \$1,000 for practicing healing without a basic science certificate. It was ordered that Awe be confined in the Olmsted County Jail until such time as the fine is paid, not exceeding six months. He was taken to jail since he was unable to pay the fine. Awe, who stated that he was one fourth Cherokee Indian, was arrested, September 14, after it was discovered that he was treating an 8 months old baby in Chester, Iowa, for eczema. He used mineral water and mineral earth, which he claimed was a cure for blindness, cancer, eczema, rheumatism, kidney trouble and many other ailments. Awe sold the mineral water at \$15 a gallon and the mineral earth at \$1 for a 4 ounce jar. The water cost him 35 cents a gallon and he obtained the earth at no expense, it was reported. He admitted that he had no training in medicine, pharmacy or any other form of healing.

MISSOURI

Society News.—The St. Louis Medical Society was addressed, September 20, by Drs. Grayson L. Carroll and Louis C. Kappel on "Sulfathiazole: A Clinical Report"; Neil S. Moore, "Cryptorchidism: Surgical Correction," and Robert W. Bartlett, "Bilateral Intercostal Nerve Block for Upper Abdominal Surgery." All are of St. Louis.

Lectures on Dermatology.—A series of lectures on dermatology opened on October 3 under the auspices of the St. Louis City Hospital number 1. Dr. Charles H. Neilson discussed "Relation of Dermatology to Internal Medicine." Dr. Joseph B. Grindon Jr., St. Louis, gave the second lecture, October 10, on "Diseases of the Scalp." October 17 Drs. Richard S. Weiss and Newell W. Schlueter discussed "The Erythemas" and "The Purpuras," respectively. Others in the series include the following St. Louis physicians:

- Drs. Martin Engman Jr. and Clinton W. Lane, October 24, Cutaneous Therapeutics.
- Dr. LeRoy Sante, October 31, X-Ray and Radium Therapy: Its Place in Dermatology.
- Drs. Adolph H. Conrad Sr. and Alexander J. Kotkis, November 7, Leg Ulcers: Classification and Treatment, and Physiotherapy—Its Use in Dermatology, respectively.
- Dr. Garold V. Stryker, November 21, Drug Eruptions.
- Dr. Norman Tobias, November 28, The Eczema and Eczematoid Eruptions.
- Dr. August A. Werner, December 5, Endocrines in Relationship to Dermatology.
- Dr. Lane, December 12, Fungous Infections: Classification, Treatment.

NEBRASKA

Mid-West Clinical Society.—The eighth annual assembly of the Omaha Mid-West Clinical Society will be held at the Hotel Paxton, Omaha, October 28-November 1, under the presidency of Dr. Charles McMartin. The speakers will include:

- Dr. Samuel Ayres Jr., Los Angeles, The Problem of Acne and Seborehical Conditions.
- Dr. Paul C. Colonna, Oklahoma City, Amputations in the Lower Extremities.
- Dr. John T. Murphy, Toledo, X-Ray Treatment in Cancer of the Skin.
- Dr. Reginald Fitz, Boston, The Changing Picture of Diabetes Mellitus.
- Dr. Verne C. Hunt, Los Angeles, Acute Conditions of the Abdomen.
- Dr. Horton R. Casparis, Nashville, Tenn., Gastrointestinal Allergy of Infants and Children.
- Dr. William E. Ladd, Boston, Acute Conditions of the Abdomen in Infancy.
- Dr. Wendell S. Muncie, Baltimore, The General Practitioner's Stake in Psychiatric Therapy.
- Dr. Harold I. Lillie, Rochester, Minn., Acute Infections of the Upper Respiratory Tract.
- Dr. George R. Herimann, Galveston, Texas, The Clinical Study of Patients.
- Dr. Joseph L. Baer, Chicago, Office Gynecological Practice.
- Dr. Roy R. Kracke, Emory University, Ga., The Toxic Effect of Drugs on the Blood.
- Dr. Frank J. Heck, Rochester, Minn., Clinical Diagnosis of the Anemias, Exclusive of Blood Studies.
- Dr. Willis M. Fowler, Iowa City, Iron Deficiency Anemias.
- Dr. Frank H. Bethell, Ann Arbor, Treatment of Pernicious Anemia.
- Dr. George M. Curtis, Columbus, Ohio, Rationale of Splenectomy in the Treatment of Certain Anemias.

In addition to the presentation of papers there will be round table discussions, clinics, lecture courses, dinner discussions and motion pictures. Thursday evening will be devoted to a meeting with the Omaha-Douglas County Medical Society; the speakers will include Chauncey S. Boucher, Ph.D., chancellor of the University of Nebraska, Lincoln, on "Perspective in Professional and General Education." Friday morning will be given over to a symposium on the anemias.

NEW JERSEY

Activities of State Medical Board.—The New Jersey Board of Medical Examiners reported the following activities of recent months:

- Dr. John F. Zielinski, Trenton, license revoked.
- Lorenzo Bello, Newark, sentenced to ten days in jail for practicing medicine without a license.
- Felicia Kornreich, Paterson, paid a penalty for practicing medicine without a license.
- Lillian Prien, Hackensack physiotherapist, paid a penalty for practicing medicine without a license.
- Gustino Coppola, Paterson pharmacist, paid a penalty for practicing medicine without a license.
- Lucia Raffone, a midwife of Newark, paid a penalty for practicing medicine without a license.
- Jack E. Allbaugh, unlicensed chiropractor of East Orange, pleaded guilty to practicing medicine without a license.

NEW MEXICO

New Director of Public Health.—Dr. James R. Scott, Albuquerque, has been appointed state director of public health. The position has been vacant for several months since Dr. Edwin B. Godfrey, Santa Fe, resigned on account of ill health. Dr. Scott, who has been professor of health education at the University of New Mexico, graduated at Cooper Medical College in 1912.

NEW YORK

Postgraduate Work Expanded.—The council committee on public health and education of the Medical Society of the State of New York has expanded its medical education program with a plan for "Teaching Days." A "Teaching Day" may be devoted to a single subject or to several subjects, with clinics conducted by eminent specialists in their fields on the afternoon of the day selected, and an evening meeting, when the visiting physicians lecture and present their subjects for general discussion. Dr. Homer F. Swift, New York, conducted such a program for the Onondaga County Medical Society, Syracuse, October 1, on rheumatic fever in cooperation with the state department of health. A similar program was presented in Rochester, October 9, for the Medical Society of the County of Monroe, with the following speakers: Drs. Russell L. Cecil, New York, on "Arthritis"; Samuel Kleinberg, New York, "Backache," and William J. Merle Scott, Rochester, "Thyroid Diseases." Dr. Oliver W. H. Mitchell, Syracuse, is chairman of the council committee.

New York City

Personal.—The library of the late W. T. H. Howe, Cincinnati, president of the American Book Company, was recently bought from his estate by Dr. Albert A. Berg and presented as a gift to the New York Public Library. The late Mr. Howe was said to have spent forty years and more than \$2,000,000 in assembling the collection. This is the second collection presented to the public library by Dr. Berg. In February he gave a group assembled by himself and his brother, the late Dr. Henry W. Berg, and, in addition, established a trust fund for its administration and care. Like the first collection, the second has been presented by Dr. Berg as a memorial to his brother.

Promotions at Long Island College.—Dr. Joseph B. L'Episcopo has been promoted to be professor of clinical orthopedic surgery at Long Island College of Medicine, succeeding Dr. Jacques C. Rushmore, who was made emeritus professor. Other promotions announced include:

- Dr. Eli Jefferson Browder, clinical professor of surgery, neurology and psychiatry.
- Drs. Stanley S. Lamm and Lewis A. Koch, clinical professors of pediatrics.
- Dr. Abraham M. Rabiner, clinical professor of neurology and psychiatry.
- Dr. Elliston Farrell, assistant clinical professor of medicine.
- Dr. Gaetano A. De Yoanna, assistant clinical professor of surgery.
- Drs. Lavin Milford Andersen and Emanuel Mendelson, assistant clinical professors of radiology.

OHIO

Faculty Changes at Western Reserve.—The following promotions in the medical faculty of Western Reserve University School of Medicine, Cleveland, among others, were announced recently:

- Dr. Claude S. Beck, to be professor of neurosurgery.
- Dr. John A. Toomey, professor of clinical pediatrics and contagious diseases.
- Dr. William R. Barney, associate clinical professor of obstetrics.
- Dr. Harold D. Green, associate professor of physiology.
- Dr. Maxwell Harbin, associate clinical professor of orthopedic surgery.
- Dr. James J. Joelson, associate clinical professor of genito-urinary surgery.
- Dr. Robert F. Parker, associate professor of medicine.
- Dr. Roger O. Egeberg, assistant clinical professor of medicine.
- Dr. Roscoe D. Leas, assistant clinical professor of medicine.
- Dr. Joseph E. McClelland, assistant clinical professor of pediatrics.
- Dr. Floyd S. Mowry, assistant clinical professor of obstetrics.
- Dr. Donald J. Rehbock, assistant professor of pathology.
- Dr. Robert M. Stecher, assistant clinical professor of medicine.

Drs. David Bodian, Baltimore, and Ernst A. Scharrer, New York, were appointed assistant professors of anatomy, among other new appointments. Dr. Bruno Gebhard, recently appointed director of the new Cleveland Museum of Hygiene, was appointed associate in health education.

OREGON

Society News.—Dr. Robert Yorke Herren, Portland, addressed the Polk-Yamhill-Marion Counties Medical Society at its September meeting on "Recognition and Treatment of Acute Craniocerebral Injuries."—Dr. Reuben H. Fields, Reedsport, addressed the Coos and Curry County Medical Society in Marshfield in September on "Cholera in China."—Dr. Ludvig Hektoen, Chicago, addressed the Portland Academy of Medicine, September 23 and 24, on "Trends of Fundamental Cancer Research" and "The Control of Cancer."

PENNSYLVANIA

State Medical Election.—Dr. Lewis T. Buckman, Wilkes-Barre, was chosen president-elect of the Medical Society of the State of Pennsylvania at its recent annual meeting in Philadelphia and Dr. Francis F. Borzell, Philadelphia, was installed as president. Other officers include Drs. John Hart

Toland, Philadelphia; Christian Gruher, Shenandoah; Walter S. Brenholtz, Williamsport, and Walter J. Stein, Ardmore, vice presidents; Dr. John B. Lowman, Johnstown, treasurer, and Dr. Walter F. Donaldson, Pittsburgh, secretary.

Philadelphia

Hospital News.—The seventy-fifth anniversary of the founding of the Jewish Hospital was celebrated at a dinner at the Bellevue-Stratford, September 23. Dr. Benjamin W. Black, Oakland, Calif., president of the American Hospital Association, delivered the principal address, discussing the hospital's position in civilization. More than 700 persons attended the dinner.

Dr. McFarland Named to Dental School.—Dr. Joseph McFarland, emeritus professor of pathology and bacteriology, University of Pennsylvania School of Medicine, has been appointed professor of general pathology at the school of dentistry of Temple University. A native of Philadelphia, Dr. McFarland graduated at the University of Pennsylvania School of Medicine in 1889. During his career he has served, among other positions, as professor of pathology at the Woman's Medical College of Pennsylvania, professor of pathology and bacteriology at the Medico-Chirurgical College of Philadelphia, continuing at the University of Pennsylvania after it took over the former school, organizer and director of the Mulford Biological Laboratory, 1894-1900, and secretary of the Section on Pathology of the American Medical Association, 1901-1903, and chairman, 1903-1904.

TEXAS

Personal.—Dr. Neil D. Buie, Marlin, president-elect of the State Medical Association of Texas, was guest of honor at a dinner and reception given by Dr. Charles M. Rosser, Dallas, September 13, to the Dallas County Medical Society. Speakers at the dinner included Drs. Thomas J. Crowe, Dallas, secretary of the state board of medical examiners, Holman Taylor, Fort Worth, secretary of the state medical association, Preston Hunt, Texarkana, president, and Dr. Buie.

Annual Fort Worth Clinics.—The annual Fort Worth Medical and Surgical Clinics presented by the Tarrant County Medical Society were held, September 24, at the Hotel Texas. The guest speakers were:

- Dr. Karl A. Menninger, Topeka, Kan., A Scientific Study of the Personality from a Medical Standpoint.
- Dr. Virgil S. Counseller, Rochester, Minn., Surgical Management of Various Types of Acute Intestinal Obstruction.
- Dr. Willard R. Cooke, Galveston, Retroversion.

At a banquet in the evening Dr. Menninger made an address entitled "Some Thoughts of a Psychiatrist Concerning War."

GENERAL

The Casselberry Prize.—The Casselberry Prize Fund of the American Laryngological Association has available \$150 to be given as an award for original work done in laryngology and rhinology. The thesis must be submitted before February 1. Further information may be obtained from Dr. Charles J. Imperatori, secretary of the association, 108 East Thirty-Eighth Street, New York.

Association of Food and Drug Officials.—The forty-fourth annual conference of the Association of Food and Drug Officials of the United States will be held at the Jung Hotel, New Orleans, October 22-25. Among the speakers will be:

- Dr. Erwin E. Nelson, New Orleans, Biologic Assays and Enforcement Activities.
- Mr. W. G. Campbell, Washington, D. C., Progress in Food, Drug and Cosmetic Control Under the New Federal Food, Drug and Cosmetic Act.
- Mr. E. L. Redfern, department of agriculture, Des Moines, Iowa, Locker Plants and Frozen Foods.
- Mr. Guy G. Frary, state chemist, Vermillion, S. D., Role of the Food and Drug Control Official in National Emergency.
- Dr. Alfonso E. Taylor, General Mills, Inc., Minneapolis, The Changing Picture of World Food Supplies.

Position Open as Director of Birmingham Hospital.—A nationwide examination will be held to fill the position of director of the new Jefferson Hospital in Birmingham, Ala. Applications may be secured from the Personnel Board of Jefferson County, Room 520, Courthouse, Birmingham. The entrance salary will be \$6,000 a year, subject to increase as the successful operation and expansion of the new hospital may justify. Tenure of office shall be at the pleasure of the county commission during the probationary period of twelve months from date of appointment, after which the appointee shall attain civil service status. Applicants shall be male citizens of the United States, within the age limits of 32 and 48

years. Preference will be given to citizens of Jefferson County who qualify. Among other things, the applicant shall have had not less than five years' experience as administrator of an approved general hospital with an average occupancy of not less than 150 patients and caring for both private and charity patients.

Plastic and Reconstructive Surgery.—The ninth annual meeting of the Society of Plastic and Reconstructive Surgery will be held at the Stevens Hotel, Chicago, October 25-26, under the presidency of Dr. Arthur Palmer, New York. The speakers will include:

- Dr. Palmer, The Development of Plastic Surgery; the Need for Improvement in Instruction.
- Dr. William Milton Adams, Memphis, Tenn., Fractures of Maxilla and Use of a New Appliance.
- Dr. Jacques W. Malinac, New York, Plastic Surgery in Warfare.
- Dr. George V. I. Brown, Milwaukee, Problems That Confronted a Plastic Surgeon in This Country During the First World War.
- Dr. Fred H. Albee, New York, Plastic Repair of Ununited Fractures of the Neck of the Femur (motion pictures).
- Dr. Harold R. Browne, Marjolin's Ulcer in Burns.
- Dr. Vilray P. Blair, St. Louis, Experiences in Plastic Surgery During the World War.
- Dr. Robert J. Alexander, Salt Lake City, Correction of Facial Paralysis by Muscle Transplant.
- Dr. Earl C. Padgett, Kansas City, Mo., Compound Injuries of the Face, Mouth and Jaws.
- Dr. Lyndon A. Peer, Newark, N. J., The Fate of Autogenous Septal Cartilage After Transplantation in Human Tissues.
- Dr. Chaire L. Straith, Detroit, Treatment of Facial Wounds Due to Explosions.

Mead Johnson & Company B Complex Award.—Nominations are solicited for the 1941 award of \$1,000 established by Mead Johnson & Company to promote researches dealing with the B complex vitamins. The recipient of this award will be chosen by a committee of judges of the American Institute of Nutrition and the formal presentation will be made at the annual meeting of the institute in Chicago April 16, 1941. The award will be given to the laboratory (nonclinical) or clinical research worker in the United States or Canada who, in the opinion of the judges, has published during the calendar year January 1 to December 31, 1940, the most meritorious scientific report dealing with the field of the B complex vitamins. While the award will be given primarily for publications of specific papers, the judges are given considerable latitude in the exercise of their function. If circumstances dictate, it may be recommended that the prize be divided between two or more persons. It may also be recommended that the award be made to a worker for valuable contributions over an extended period but not necessarily representative of a given year. Membership in the American Institute of Nutrition is not a requisite of eligibility for the award. To be considered by the committee of judges, nominations for this award for work published in 1940 must be in the hands of the secretary by Jan. 25, 1941. The nominations should be accompanied by such data relative to the nominee and his research as will facilitate the task of the committee of judges in its consideration of the nominations. Leonard A. Maynard, Ph.D., Laboratory of Animal Nutrition, Cornell University, Ithaca, N. Y., is the secretary of the institute.

Government Services

Public Health Service Needs Bacteriologists

The U. S. Civil Service Commission announces competitive examinations for bacteriologists for the U. S. Public Health Service. The grades included in the examination are associate bacteriologist, \$3,200 a year, and assistant bacteriologist at \$2,600 a year, less a retirement deduction of 3.5 per cent. Appointments will be made for the staff of the Rocky Mountain Laboratory at Hamilton, Mont., and other places. Applications must be filed with the commission's Washington office not later than November 12 if received from states east of Colorado, and not later than November 15 if received from Colorado and states westward. Applicants must have completed a four year college course, including twenty-four semester hours of study in bacteriology, and, in addition, postgraduate study or experience in advanced bacteriologic work. Applicants will be rated on their qualifications as shown in their application and on corroborative evidence and not on a written test. Further information may be obtained from the secretary of the Board of U. S. Civil Service Examiners at any first or second class post office or from the U. S. Civil Service Commission, Washington, D. C.

Foreign Letters

LONDON

(From Our Regular Correspondent)

Sept. 21, 1940.

The Attacks on London from the Air

Sporadic raids have been followed by daily attacks on London since September 7, which have caused considerable damage to property and casualties which, though serious, are small for the population of 8 million. The reason is that our defenses are so good that they have prevented massed attacks by breaking up these before they reach the capital. Hence most of the damage is done by a few night raiders, whose bombing is indiscriminate. The following official figures are available: During the first half of September about 2,000 civilians, men and women and children, were killed in Britain in air raids and about 8,000 were wounded. Four fifths of these casualties occurred in London. The indiscriminate nature of the attacks is shown by the fact that only 250 of the 10,000 casualties occurred in the fighting forces. Many of the great hospitals of the metropolis have been damaged. The largest hospital, the London, was hit by three bombs in a fortnight. A high explosive shell fell in a yard between the physical medicine department and a first aid post. The only casualties were two nurses, who were slightly hurt by splinters. At the Westminster Hospital, which specializes in radium treatment, two radium bombs containing 6 Gm. are in use. Every time the London sirens sound a warning, which now occurs several times in the twenty-four hours, these bombs are lowered to the bottom of a 50 foot well, where they remain in safety until the "all clear" is sounded. High voltage roentgen treatment has also had to stand by during the raids. The hospitals have also suffered from incendiary bombs, and doctors and nurses have helped in the extinction of the fires caused.

The bearing and spirit of the Londoners under the ordeal has won the admiration of visitors from other countries. They show the toughness and tenacity characteristic of the British in the face of danger. From all over the metropolis come stories of the heroism of doctors and nurses in the dangerous work of helping the injured during air raids. Not only are medical services working efficiently but the government has made every provision for those rendered homeless by the destruction of their dwellings, providing billets and food. In normal times the authorities have to do all that is possible to maintain the health and well-being of an enormous population living under artificial urban conditions. War has produced new problems on a large scale and our services are bearing the strain well. Our whole system of life and labor is being rapidly adapted to conditions hitherto unknown to modern society. Damage of roads and of water, gas and electrical power mains have to be quickly remedied. While the transport system of London is generally working well, of course there are some inconveniences. Thus a delayed action bomb has put a railway station out of use. The difficulty is surmounted by making the railway tickets available for road transport corresponding to a section of the line. Contrary to enemy statement, the food supply of London is abundant and the now controlled distribution works without any friction.

Drug Restriction from the War

The policy of the government is that tonnage and foreign currency should not be used to import drugs which are not essential or for which substitutes can be obtained at home. An advisory medical committee has prepared lists of drugs classified as follows: (1) essential drugs, (2) drugs essential for certain purposes but the use of which should be restricted

and (3) nonessential drugs, which should not be imported or manufactured in wartime. A long list of the first class includes glycerophosphoric acid, tartaric acid, tolu balsam, apocynum, cantharides, cinnamon, copaiba, jalap, senega, strophanthus, tamarind, taraxacum and camphor. In a number of cases substitutes are suggested. Thus, in place of aconite, ethyl aminobenzoate is suggested for local application. For buchu, copaiba, cubeb and santal oil are suggested sulfanilamide, methenamine, mandelic acid, sodium benzoate and scoparius. Hydrochloric acid and sodium bromide may be used for hydrobromic acid; citric for tartaric acid; quassia for calumba and gentian; mustard for cantharides; dill for caraway seed; male fern and carbon tetrachloride for kousso and pelletierine tannate; synthetic analgesics for gelsemium; tannic acid for hamamelis and krameria; colocynth for jalap; sodium salicylate for stramonium; turpentine for camphor oil; methyl salicylate for salicin; Indian squill for squill; iodides, ammonium carbonate and ammonium chloride for senega, and digitalis for strophanthus.

The Food Situation in Europe

As stated in previous letters, the supply of food in Britain is plentiful, thanks to our command of the sea and to increased agricultural production. Meat, sugar and butter are rationed, but this is only a small inconvenience, as other foods are unrestricted. But on the European continent the ravages of war have impaired production and now the enslaved peoples are being ruthlessly plundered by the invaders, so that there

Weekly Rationing, in Ounces, of Germany and Countries Occupied by German Forces

	Bread	Meat	Sugar	Fats	Coffee
Germany.....	80	17½	8	10½	3½ (substitute)
Protectorate....	44	17½	10½	5½	3½
Poland.....	35	9	5½	2½	?
France.....	Restricted	Restricted	4½	2	Restricted
Denmark.....	Restricted	Restricted	13	4	Restricted
*Norway.....	Restricted	Restricted	9	10½	1½
*Netherlands....	71	Restricted	9	4½	1½
Belgium.....	56	Restricted	7½	13½	3

* Supplies usually not equal to official rations.

is privation even in the countries which normally are great food exporters. The accompanying table, published by the *Times*, gives the weekly rationing in ounces and shows the disparity between the German rations and those of the enslaved peoples. Later information supplies the following figures for France: meat 12½ ounces and cheese 1½ ounces weekly; bread 12¼ ounces daily; sugar 17½ ounces and rice 3½ ounces monthly. In every country that they have overrun the Germans have commandeered outright nearly all the food reserves and ordered slaughtering of much of the livestock. During the week of September 16 to 22 alone Germany took from the little country of Denmark, without even the pretext of war, 17,000 sheep and 11,000 head of cattle. Holland lost nine tenths of her large butter reserves in a week and out of 28,000,000 poultry 22,000,000 are ordered to be slaughtered this autumn. Only the other day the German wireless boasted that Germany had taken 43,000,000 Kg. of early potatoes from the Netherlands in three months. From Norway Germany takes 200 tons of fish daily and from Belgium all the available eggs, the Belgian producers having been warned of penalties should they sell without a German controlled license. From the enslaved countries Germany has added 2,000,000 tons of wheat to her reserves and has just demanded 780,000 tons from France. These facts, which might be multiplied, should be remembered when German propaganda states that the food shortage of enslaved Europe in the coming winter is due to the British blockade.

BUENOS AIRES

(From Our Regular Correspondent)

Sept. 13, 1940.

Care of Persons with Heart Disease

Extensive statistically supported studies have been made by Dr. Rafael A. Bullrich, professor of internal medicine in Buenos Aires, on the incidence of heart disease in persons over 60 years of age. The mortality rate from circulatory diseases at all age levels for the last ten years amounted to 29 per cent of the general death rate; for persons between 60 and 80 years it rose to 43.38 per cent. If deaths from chronic nephritis are included, and these are caused almost altogether by heart disease in persons past 60, the mortality rate for 1939 from heart disease was as high as 47 per cent for this age group. It is assumed that in Argentina's total population of about 13,500,000 there are about 540,000 persons 60 years and older. Including latent cases in which exertion is an involving factor only on a small scale, it is estimated that more than 44 per cent of these, about 237,000, suffer from cardiac lesions. At any rate the high percentage of those affected discloses the social significance of this disease. The fact that institutions cannot provide sufficient beds does not make the problem easier for the families. Members of pension funds, such as state employees, are better off. According to Bullrich's previous investigations, more than 40 per cent of those receiving pensions from funds such as working men's insurance funds and railroad pension funds have been retired because of circulatory diseases, and the morbidity rate seems to be on the increase. Many who have contracted cardiac abnormalities through a life of struggle and strain and are not members of pension funds are helpless if without means, since there are no state provisions such as exist in Uruguay with its pension law for the aged, in the United States of America and in several European countries where social welfare laws in some form or other benefit aged persons with heart trouble. This problem is all the more pressing as the number of the aged is increasing in Argentina. Bullrich favors old age insurance, the costs of which are to be defrayed by a special tax as a preliminary step, until fuller plans of social legislation can be worked out.

The Asistencia social del cardíaco, a voluntary organization founded in 1938 for the purpose of aiding persons with heart disease and directed by Bullrich, arranges hospitalization when necessary, takes care of pregnant women, nursing mothers and children with cardiac lesions, and vocationally guides the latter. It seeks to provide homes for those completely disabled, for those for whom their nearest relatives cannot care and for those who, though improved, need continued care. It promotes the organization and equipment of dispensaries and colonies, urges increased legislation favoring workers and employees affected with disorders of the heart, furthers special schools of vocational training and arranges locations where articles made can be sold. The Asistencia social del cardíaco, under the control of the Public Aid of the city of Buenos Aires, has so far called into being nine dispensaries that are housed in the different hospitals of the city. In this work it has the cooperation of the Asociación de damas cooperadoras de la asistencia social al cardíaco. This group of cooperating women pays the rentals, distributes medicines, food and clothing and sends children of incapacitated persons into summer camps. Funds are raised by voluntary offerings on annual tag days.

Recently a society for the study of social aid to cardiac persons, also under the direction of Bullrich, was organized. It includes the physicians who are active in the dispensaries and those consulted by the Public Aid in problems concerning rheumatism. The first national congress dealing with social

problems arising from heart disease will meet during the month of November in Buenos Aires. Physicians from Brazil and Uruguay will participate.

Medical Research Institute of Colombia

The Federico Lleras Institute of Medical Investigation in Bogotá, Colombia, named after its founder, Prof. Federico Lleras Acosta, and since 1934 under the direction of Dr. Luis Patiño Camargo, is chiefly engaged in leprosy research, though not entirely so. It has departments of bacteriology, serology, biochemistry, pathologic anatomy, clinics and therapy. It tests the scientific results achieved in other countries and examines new therapies. The institute recently moved into specially designed quarters, composed of three wings housing the laboratories and the clinics. Its annual budget amounts to 30,000 Colombian pesos (about \$17,000).

Association of Argentine Hospitals

Argentina's delegates to the Hospital Congress that met in Toronto in September 1939 have officially submitted recommendations counseling the organization of the Asociación argentina de hospitales, to include existing hospital associations. The other Spanish-American countries are likewise to be encouraged to form similar organizations. Organization plans under the direction of Dr. José W. Tobías, president of the Public Aid of Buenos Aires, are already under way. The association will not be concerned with scientific matters but only with purely administrative problems.

Society News

The third Chilean and American Congress for Surgery (Congreso Chileno y Americano de Cirugía) will meet in February 1941 on the occasion of the four hundredth anniversary of the founding of Santiago. Papers will be read also by physicians from Argentina, Uruguay and Peru.

The second American Congress for Endocrinology will meet in Montevideo, Uruguay, March 5 to 8, 1941. This congress has the active support of the government. The arrangement committee is headed by Dr. Juan C. Mussio Fournier, minister of public health.

In Santiago de Chile a new building is being erected for the Bacteriologic Institute of Chile. It is planned on a large scale and will have laboratories for the study of vitamins and hormones besides departments of bacteriology, serology, biochemistry and chemotherapy. Dr. E. Friedheim, privatdozent of the University of Geneva, has been invited by the ministry of public health to organize the chemical division.

Marriages

ALBERT MAXWELL BETCHER, Jersey City, N. J., to Miss Gertrude Weinberger of New York, September 22.

FRANCIS BENEDICT LANAHAN, Narberth, Pa., to Miss Rita Virginia Byrne of Phoenixville, September 14.

GEORGE EDMUND STONE, Staunton, Va., to Miss Frances Elizabeth Fitzpatrick of Radford, July 27.

FRANKLIN P. LE VAN, Chicago, to Dr. GRACE C. ILIFF of Ottawa, Ill., in St. Louis, September 5.

EDWARD SCHUMACHER to Miss Margaret Stucky, both of Cleveland, in Lakewood, Ohio, July 20.

JAMES M. HINDLEY to Miss Marjorie Stewart, both of Monroeville, Ohio, at Pittsburgh in June.

ERWIN EMANUEL PETERS to Miss Ann Katherine Harris, both of Baltimore, September 9.

JOSEPH J. NOTO, Baton Rouge, La., to Miss Angelina Marie Macheca of New Orleans, July 31.

LYNNE E. BAKER, Cincinnati, to Miss Elizabeth Titus of Fond du Lac, Wis., September 5.

ALLEN H. BUNCE to Miss Isabella Washington Arnold, both of Atlanta, Ga., June 12.

Deaths

Francis Park Lewis * Buffalo; Pulte Medical College, Cincinnati, 1876; member of the American Academy of Ophthalmology and Otolaryngology, American Ophthalmological Society, Association for Research in Ophthalmology, French Ophthalmological Society and the German Ophthalmological Society; fellow of the American College of Surgeons; past president of the Buffalo Academy of Medicine; was chiefly responsible for the founding of the National Society for the Prevention of Blindness in 1908 and the International Association for Prevention of Blindness in 1929; served as vice president of both organizations since their founding; in 1928 was awarded the Leslie Dana Gold Medal by the St. Louis Society for the Blind in recognition of outstanding achievements in the prevention of blindness and the conservation of vision; received a special gold medal from the International Association for the Prevention of Blindness in London in April 1939; in 1933 received the chancellor's medal from the University of Buffalo, awarded annually to the citizen considered most deserving of community recognition; ophthalmic surgeon to the Millard Fillmore Hospital; oculist to the Buffalo State Hospital; consulting ophthalmologist to the Buffalo City and Erie County hospitals, Buffalo, and the J. N. Adam Memorial Hospital, Perrysburg; president of the New York School for the Blind, Batavia, for many years; one of the editors of the *American Journal of Ophthalmology*; author of books, and of many papers in scientific journals, as well as the translator into English of many scientific articles from the German, French, Italian and other languages; one of the contributors to the American Encyclopedia of Ophthalmology; ophthalmic examiner during the World War; aged 85; died, September 10, in the Mather Memorial Hospital, Port Jefferson.

Phoebus A. Theodore Levene, New York; Imperial Military Medical Academy, St. Petersburg, Russia, 1891; in 1905 assistant in chemistry and since 1907 member, Rockefeller Institute for Medical Research; associate in chemistry at the State Pathological Institute of New York from 1896 to 1905; chemist to the Saranac Laboratory for the Study of Tuberculosis, Saranac Lake, N. Y., from 1900 to 1902; Herter lecturer of pathologic chemistry at the New York University, 1905-1906; received the Willard Gibbs Medal from the Chicago Section of the American Chemical Society in 1931 and the William H. Nichols Medal from the New York Section of the American Chemical Society at the meeting in 1938; was a member of numerous scientific societies; author of papers and monographs; aged 71; died, September 6, of coronary occlusion.

George Washington Goler, Rochester, N. Y.; University of Buffalo School of Medicine, 1889; medical inspector, board of health of Rochester, from 1892 to 1896 and health officer from 1896 to 1932; was lecturer in preventive medicine at the University of Rochester School of Medicine and Dentistry; served during the World War; was largely responsible for the erection of the Municipal Hospital; honorary president of the fourth section of the International Congress of Child Hygiene in Berlin, Germany; member of the board of managers of the New York State Industrial School from 1896 to 1900; aged 76; died, September 18, in the Strong Memorial Hospital of hemorrhage due to duodenal ulcer and bronchopneumonia.

Thomas Leidy Rhoads * Colonel, U. S. Army, retired, Boyertown, Pa.; Jefferson Medical College of Philadelphia, 1893; was an assistant surgeon in the U. S. Navy from June to November 1898; entered the army as an assistant surgeon in 1900 and was promoted through the various grades to that of colonel in 1926; retired May 31, 1931, at his own request after thirty years' service; veteran of the Spanish American War; was awarded the Distinguished Service Medal for service during the World War; fellow of the American College of Surgeons; personal physician and personal aide-de-camp to President Taft; aged 70; died, August 20, of coronary occlusion.

Cecil Dulin Gaston * Birmingham, Ala.; Jefferson Medical College of Philadelphia, 1910; member of the American Proctologic Society and the Southeastern Surgical Congress; fellow of the American College of Surgeons; past president of the Jefferson County Medical Society; served in different capacities on the staff of the Hillman Hospital; on the staff of the South Highlands Infirmary; formerly on the staffs of St. Vincent's and the Baptist hospitals; served during the World War; editor of the Transactions-American Proctologic Society, 1932-1933; aged 52; died, September 12, of myocarditis and nephritis.

Mary M. S. Johnstone * Chicago; Northwestern University Woman's Medical School, Chicago, 1899; taught gynecology and obstetrics at Northwestern University from July 1900 to June 1901 and at Rush Medical College from 1908 to 1910 and again from 1913 to 1917; during the World War served as a contract surgeon from Aug. 13, 1918, to July 2, 1919; following this service she entered the Veterans Bureau; on the staff of the Veterans Administration Facility, Hines, Ill.; aged 69; died, September 1, of gastrointestinal disease.

Stephen Haskell Blodgett, South Lincoln, Mass.; Harvard Medical School, Boston, 1887; member of the Massachusetts Medical Society; at one time clinical professor of venereal diseases, Boston University School of Medicine; served during the World War; formerly member of the board of health; aged 77; was killed, September 3, at Batavia, N. Y., when the automobile in which he was riding was struck by a truck.

Charles Dwight Pullen, Mount Pleasant, Mich.; University of Michigan Homeopathic Medical School, Ann Arbor, 1892; member of the Michigan State Medical Society; for many years member of the board of education; formerly member of the state legislature; served during the World War; aged 74; died, August 27, in the Good Samaritan Hospital, Bay City, following an operation for gallstones.

Henry Madison Tolleson, Eastman, Ga.; Emory University School of Medicine, Atlanta, 1928; member of the Medical Association of Georgia; received the Crawford W. Long Memorial Prize from the Medical Association of Georgia in 1931; past president of the Ocmulgee Medical Society; on the staff of the Coleman Sanatorium; aged 37; died in August of carbon monoxide poisoning, self administered.

Harry Ellsworth Welch, Youngstown, Ohio; Western Reserve University Medical Department, Cleveland, 1885; fellow of the American College of Physicians; past president of the Mahoning County Medical Society; for many years city health officer and formerly coroner; aged 78; on the staff of the Youngstown Hospital, North Side Unit, where he died, August 12.

Margaret Pauline Harrison Bowden * New Orleans; Tulane University of Louisiana School of Medicine, New Orleans, 1919; member of the American Society of Clinical Pathologists; on the staffs of the Touro Infirmary and the Charity Hospital; aged 63; died, August 5, of myocarditis and pneumonia following influenza.

Mary Ella Dunning Rose, Orange, N. J.; Woman's Medical College of Pennsylvania, Philadelphia, 1896; member of the Medical Society of New Jersey; formerly member of the board of education; aged 68; died, August 29, in the Presbyterian Hospital, Newark, of cerebral hemorrhage.

Randolph Ora Stites, Industry, Ill.; Chicago College of Medicine and Surgery, 1916; member of the Illinois State Medical Society; served during the World War; aged 50; died, September 1, in the Marietta Phelps Hospital, Macomb, of a hemorrhage due to a gastric ulcer.

Hugh Lenox Hodge Dick * Darby, Pa.; Jefferson Medical College of Philadelphia, 1909; on the staffs of the Fitzgerald-Mercy Hospital, Darby, and the Delaware County Hospital, Drexel Hill; aged 57; died, September 11, in the Phoenixville (Pa.) Hospital of coronary thrombosis.

Ferdinand Augustus Binford, Hyannis, Mass.; Harvard Medical School, Boston, 1899; member of the Massachusetts Medical Society; for many years on the staff of the Cape Cod Hospital; aged 69; died, September 1, of chronic myocarditis and diabetes mellitus.

Alexander Angus Beaton * Franklin, N. H.; Dartmouth Medical School, Hanover, 1898; on the staff of the Franklin Hospital; formerly mayor; aged 68; died in August at Flat River, Prince Edward Island, of cerebral hemorrhage and heart disease.

William Gray Phillips Jr., New York; Long Island College Hospital, Brooklyn, 1912; served during the World War; aged 50; died, August 24, in the United States Marine Hospital, Stapleton, of rheumatic heart disease and subacute bacterial endocarditis.

Joseph Adhemar Brien, Montreal, Que., Canada; M.B., Laval University Medical Faculty, Montreal, 1890, and M.D., 1892; appointed to the municipal health service in 1921 and made superintendent in 1929, retiring in 1939; aged 71; died, July 12.

Charles Rowland Stewart, Millvale, Pa.; University of Pennsylvania Department of Medicine, Philadelphia, 1899; member of the Medical Society of the State of Pennsylvania; aged 67; died, August 31, in the St. Francis Hospital, Pittsburgh.

Clarence Vernon Page, St. Paul; State University of Iowa College of Homeopathic Medicine, Iowa City, 1902; member of the Minnesota State Medical Association; aged 65; died, August 28, of pulmonary tuberculosis and arteriosclerosis.

John Coskery Wright, Augusta, Ga.; University of Georgia Medical Department, Augusta, 1908; member of the Medical Association of Georgia; professor of clinical gynecology at his alma mater; aged 57; died in August at Beaufort, S. C.

Joseph E. Smith, Brooklyn; Jefferson Medical College of Philadelphia, 1875; for many years chief medical officer of the fire department of New York City; aged 87; died, August 22, in Ridgewood, N. J., of carcinoma of the sigmoid.

Clyde Edwin King, Chicago; Chicago College of Medicine and Surgery, 1907; member of the Illinois State Medical Society; aged 67; on the staff of the Jackson Park Hospital, where he died, September 1, of myocarditis.

Thomas Lincoln Jenkins ♂ Topsfield, Mass.; Harvard Medical School, Boston, 1890; veteran of the Spanish-American and World wars; aged 73; died, July 29, in Crawford, Maine, of coronary thrombosis and arteriosclerosis.

William Earl Hutto, Atlanta, Ga.; Emory University School of Medicine, Atlanta, 1931; member of the Medical Association of Georgia; aged 36; was killed, August 31, in an automobile accident near Demopolis, Ala.

Clarence Arlington Weaver ♂ Washington, D. C.; Jefferson Medical College of Philadelphia, 1892; veteran of the Spanish-American War; aged 69; died, August 23, of acute dilatation of the heart and hypertension.

Charles Kendall Small, San Leandro, Calif.; Hahnemann Hospital College of San Francisco, 1896; Hahnemann Medical College and Hospital, Chicago, 1897; aged 64; died, August 15, of hypertension and coronary thrombosis.

Homer G. Rosenberger ♂ Whittier, Calif.; Rush Medical College, Chicago, 1907; served during the World War; fellow of the American College of Surgeons; aged 60; died, August 14, in Los Angeles of cerebral thrombosis.

Charles Gailey Brown Sr. ♂ Mansfield, Ohio; Jefferson Medical College of Philadelphia, 1901; fellow of the American College of Surgeons; on the staff of the Mansfield General Hospital; aged 65; died, September 2.

George Vincent Duffy, Queens Village, N. Y.; Fordham University School of Medicine, New York, 1912; member of the Medical Society of the State of New York; aged 55; died, September 6, of coronary thrombosis.

Philip Leibowitz ♂ Brooklyn; Long Island College Hospital, Brooklyn, 1913; member of the American Academy of Ophthalmology and Otolaryngology; on the staff of the Jewish Hospital; aged 52; died, August 29.

Michael Lester Casey, Rochester, N. Y.; University of Pennsylvania Department of Medicine, Philadelphia, 1898; served during the World War; aged 70; died, August 6, of carcinoma of the stomach.

James V. Denny, Sullivan, Mo.; Beaumont Hospital Medical College, St. Louis, 1896; aged 71; died, September 10, at the Missouri Baptist Hospital, St. Louis, of pericarditis and chronic cholecystitis with stones.

Oscar Benjamin Feldser ♂ Harrisburg, Pa.; Jefferson Medical College of Philadelphia, 1933; aged 43; on the staff of the Harrisburg Hospital, where he died, September 5, of carcinoma of the prostate.

Harlow Robert Street, Washington, D. C.; Georgetown University School of Medicine, Washington, 1891; aged 75; died, August 23, in the Sibley Memorial Hospital of uremia and chronic nephritis.

Brady B. Buck, Canton, Ohio; Western Reserve University Medical Department, Cleveland, 1902; member of the Ohio State Medical Association; aged 63; died, September 8, of coronary thrombosis.

John Henry Cipperly, Irvington, N. Y.; University of the City of New York Medical Department, 1879; for many years health officer of Troy, N. Y.; aged 83; died, July 17, of coronary occlusion.

Atwater Lincoln Douglass, Denver; Hahnemann Medical College and Hospital of Philadelphia, 1895; member of the Colorado State Medical Society; aged 71; died, August 24, in Ellsworth, Kan.

Coleman J. Eads, Oklawka, Ill.; University of Louisville (Ky.) Medical Department, 1890; member of the Illinois State Medical Society; aged 74; died, September 4, of a self-inflicted bullet wound.

John Hampton Murphey, Opal, Ark. (licensed in Arkansas in 1904); member of the Arkansas Medical Society; past president of the Polk County Medical Society; aged 62; died, August 14.

George Wesley Hall, Little Britain, Ont., Canada; M.B., University of Toronto Faculty of Medicine, 1895, and M.D., Trinity Medical College, Toronto, 1895; aged 75; died, July 7.

Welby Adams Colyer, Garrett, Ill.; Barnes Medical College, St. Louis, 1899; member of the Illinois State Medical Society; aged 66; died, September 8, of coronary thrombosis.

Russell Brooks Kilpatrick, Memphis, Tenn.; Memphis Hospital Medical College, 1901; also a druggist; served during the World War; aged 61; died, August 26, of angina pectoris.

Anson Torence Miller, Clinton, Iowa; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1904; aged 65; died, July 12, of septicemia.

William M. Kemp, Marietta, Ga.; Southern Medical College, Atlanta, 1889; member of the Medical Association of Georgia; aged 78; died, July 28, in Milledgeville.

Elam Rust Wright, Alton, N. H.; Dartmouth Medical School, Hanover, 1896; aged 73; died suddenly, August 23, at Ridgewood, N. J., of coronary occlusion.

William H. Badger, St. Louis; Homeopathic Medical College of Missouri, St. Louis, 1894; aged 74; died, September 10, of myocarditis and arteriosclerosis.

James S. Cochran, Norcross, Ga.; Georgia College of Eclectic Medicine and Surgery, Atlanta, 1901; aged 64; died, August 27, of bronchogenic carcinoma.

George Washington Willett, Atlanta, Ga.; Bellevue Hospital Medical College, New York, 1893; aged 72; died, August 13, of cardiovalvular disease.

Claude Calvin Snodgrass, Sand Fork, W. Va.; University of Louisville (Ky.) School of Medicine, 1909; aged 58; died, August 17, of cerebral hemorrhage.

Clare Montgomery Bennett, Nelson, B. C., Canada; University of Toronto Faculty of Medicine, 1933; aged 31; was accidentally drowned, July 29.

Ulysses Grant Bickell, Upper Darby, Pa.; Jefferson Medical College of Philadelphia, 1893; served during the World War; aged 75; died, August 4.

Rufus Milton Higgins, Oakland, Calif.; College of Physicians and Surgeons of San Francisco, 1901; formerly health officer; died, August 31.

George William Ogilvie Dowsley, Beaverton, Ont., Canada; University of Toronto Faculty of Medicine, 1899; aged 62; died, July 23.

Ernest Madison Burns ♂ Huntington Park, Calif.; University of Nebraska College of Medicine, Omaha, 1921; aged 46; died, August 18.

Necy Lewis Gachet, Midway, Ala.; University of Alabama School of Medicine, 1914; served during the World War; aged 49; died, August 6.

Benjamin Eugene Franklin, Pulaski, Tenn.; Barnes Medical College, St. Louis, 1896; also a minister; aged 74; died, August 27.

Oswell E. Morin ♂ Chicago; University of Illinois College of Medicine, Chicago, 1919; aged 48; was drowned, July 28, at Aurora, Ill.

Rebecca Rhoads Billings, Chicago; Northwestern University Woman's Medical School, Chicago, 1899; aged 67; died, July 3.

Elra W. Cook, Dallas, Texas (licensed in Texas by years of practice); aged 55; died, September 4, of pulmonary tuberculosis.

Albert Louis Bork ♂ West Allis, Wis.; Marquette University School of Medicine, Milwaukee, 1929; aged 41; died, July 20.

Curtis David Leister, Center Point, Ark. (licensed in Arkansas in 1903); aged 65; died, July 27, of cerebral hemorrhage.

Lysle Edward Haverfield ♂ Hardin, Mont.; St. Louis University School of Medicine, 1921; aged 44; died, July 29.

Julius Franklin Peavy Sr., Atmore, Ala.; Medical College of Alabama, Mobile, 1888; aged 79; died, July 19.

Benjamin F. Overton, Mexia, Texas; Louisville (Ky.) Medical College, 1886; aged 85; died, July 24.

Sidney J. Burnum, Scottsboro, Ala.; Medical College of Alabama, Mobile, 1887; aged 74; died, July 30.

Correspondence

INTRATHECAL ADMINISTRATION OF TETANUS ANTITOXIN

To the Editor:—In *THE JOURNAL*, September 7, page 888, appeared a review of a paper by W. M. Firor (Intrathecal Administration of Tetanus Antitoxin, *Arch. Surg.* 41:299 [Aug.] 1940). On the basis of his experiments on dogs, and the clinical reports of Yodh and of Vener, the author felt warranted in urging intrathecal injection by cisternal or lumbar routes of antitetanus serum in early mild or moderately severe tetanus instead of using intravenous routes, although he plans further investigation into the subject, using more highly purified serums. I do not feel that this recommendation should be adopted at present without serious reservation.

As Firor mentions, Dietrich records severe reactions on utilizing the intrathecal route. J. M. Wainright (Incidence and Treatment of Tetanus, *ibid.* 12:1062 [May] 1926), recognized the possibility of serious developments with intrathecal therapy, stating "The best way to increase the mortality of tetanus is to give antitoxin intrathecally." In two papers (Tetanus with Total Hemolysis, *Pennsylvania M. J.* 41:16 [Oct.] 1937, abstracted in *THE JOURNAL*, Dec. 11, 1937, page 2021, and Death in Tetanus: The Phenomenon of Toxin-Release, *Canad. M. A. J.* 38:460 [May] 1938), I reported six cases in which tetanus antitoxin serum was administered. In three of these the serum was injected intravenously, resulting in total hemolysis and death in one mild case of tetanus and in partial hemolysis in two cases of gas gangrene. In the remaining three, all of mild tetanus, antitetanus serum in addition was given intrathecally, one under chloroform anesthesia, resulting almost immediately in extremely severe "tetanismus" and death within an hour.

These reactions do not appear to have been anaphylactic or part of a serum sensitization. The late A. P. C. Ashhurst, in discussing the deaths which followed the intrathecal injection of antiserum, felt that they were not due to anaphylactic shock but rather to an unusual development of acute tetanus. In all six cases prophylactic antitetanus serum had been given at least ten days prior to active therapy. This afforded a period within which protein sensitization might occur. Only one of the six cases showed a positive reaction for serum sensitization, and routine desensitization had no effect whatever on the subsequent reactions, regardless of whether the intravenous or the intrathecal route of administration was chosen. It is to be noted, however, that intravenous injection resulted in hemolysis and cardiovascular collapse, suggesting the action of a hemolysin, which is one of the products of tetanus, together with indications of spasticity in several cases. Intrathecal administration resulted abruptly in "tetanismus," recorded as being identical with severe and terminal tetanus as produced by tetanospasmin. It is possible that these reactions either are caused by interaction between an amboceptor and an antiamboceptor, accentuating the disease complex, or are an unusual form of the Arthus phenomenon. In any case they may be expected to occur violently in a person who previously has received an antiserum and, after the period required for sensitization, is given a subsequent injection of identical serum in a site for which the original toxin displays an affinity. Reactions apparently cannot be anticipated by tests for serum sensitization or prevented by routine desensitization. Alterations of red cells or hemolysis when a drop of antiserum is added to a coverslip specimen of the patient's blood should give warning of some dangers threatening with intravenous administration. But there seems to be no way of anticipating serious consequences in using the intrathecal route for a patient who has previously received antitetanus serum. It is probable

that the use of heterologous serums will not exclude these reactions. For these reasons, then, when the foregoing conditions are present, I do not feel that the intrathecal administration of antitetanus serum should be advocated at present. Furthermore, antitetanus serum, administered intravenously under similar circumstances, bears serious potentialities which must be carefully guarded against or avoided by using antiserum diluted in physiologic solution of sodium chloride and given by the intramuscular routes, in combination with sedatives, particularly avertin with amylen hydrate, which has found favorable acceptance in the treatment of this disease.

W. E. B. HALL, M.D., Denver.

"REHABILITATION FOLLOWING ACUTE CORONARY ARTERY OCCLUSION"

To the Editor:—Master and Dack, the authors of the article "Rehabilitation Following Acute Coronary Artery Occlusion" (*THE JOURNAL*, Sept. 7, 1940, p. 828), base their claims on their belief that "coronary occlusion is the end result of a progressive arteriosclerotic process, . . ." which process is not related to activity. I take exception to the concept that it is unrelated to activity.

I have never seen a case of acute coronary occlusion in a really sedentary person except as secondary to diabetes or hypertension. The patient may have been retired as to occupation but not as to activity. He may have suffered severe mental anguish or been subjected to physical exertion unrelated to occupation but just as real in the effect on his physical well-being.

The authors stress the losses to insurance companies for claims wherein the patients might have been rehabilitated. Those patients who have returned to work following coronary occlusion will find themselves ineligible for insurance without even as much as legal recourse. Would the authors recommend the so-called rehabilitation cases as "good insurance risks?"

The authors speak of coronary occlusion without regard to the presence or absence of myocardial infarction. An article which disregards the severity of the injury to the heart but speaks of occlusions as if a fixed standard could be applied to them cannot scientifically conclude rehabilitation possibilities. Surely the ten patients who worked through the entire attack did not have infarction and ought not to be classed for such important statistics with the patients who suffered severe infarction.

One might observe from table 6 in the article that of 230 ward patients 123 were workers and laborers, while of 185 private patients only twenty were workers and laborers. This explains why 42 per cent of the private patients resumed full time work as against 23 per cent of the ward patients. There is a definite relationship here indicating an inability to resume occupations taxing the heart.

Furthermore, because the authors themselves admit that those who do not return to work have conditions of great severity, table 10 of the article loses most of its value. Perhaps many of the recurrences might have been avoided in the milder cases if there had not been a resumption of former activities. There can be only one measure of fitness to resume former activity after an attack of coronary occlusion; that measure is the damage to the heart muscle incurred in the individual case. The indication of the condition of the injured heart can be ascertained by the amount of activity the patient can resume without experiencing fatigue. The total evidence lies with the patient himself, since there is no means of measuring the mechanical efficiency of the heart and since even a normal electrocardiogram does not necessarily mean an efficient heart.

HYMAN RAPAPORT, M.D., Los Angeles.

Queries and Minor Notes

THE ANSWERS HERE PUBLISHED HAVE BEEN PREPARED BY COMPETENT AUTHORITIES. THEY DO NOT, HOWEVER, REPRESENT THE OPINIONS OF ANY OFFICIAL BODIES UNLESS SPECIFICALLY STATED IN THE REPLY. ANONYMOUS COMMUNICATIONS AND QUERIES ON POSTAL CARDS WILL NOT BE NOTICED. EVERY LETTER MUST CONTAIN THE WRITER'S NAME AND ADDRESS, BUT THESE WILL BE OMITTED ON REQUEST.

TROPICALLY ACQUIRED PARASITIC INFECTION AND PREGNANCY

To the Editor:—A married woman aged 25, who returned from Nicaragua after having lived there for two years, engaged me as her physician during her pregnancy. She was five and one-half months pregnant. Her health had previously been quite good and her physical examination was normal except for a severe anemia, hemoglobin being 55 per cent and the red blood count 2,800,000. The differential blood count was normal. After a week the patient suddenly suffered severe epigastric pain, vomiting and diarrhea with a slight amount of blood in the stools. One hour after the onset of pain, the patient went into shock. She required intravenous dextrose and blood transfusion. Twenty-four hours later she was fully recovered. A stool examination revealed both *Ascaris lumbricoides*, *Trichuris trichiura* and the ova of both. Should I pursue a policy of watchful waiting and attempt to eradicate the parasites after the birth of the baby or should I give an anthelmintic at once? If so, what vermifuge could be used with safety at this stage of her pregnancy and in what dosage? M.D., Pennsylvania.

ANSWER.—This case is interesting from several clinical points of view. First of all, residence of a year or more in tropical America on the part of citizens of the United States frequently results in disease, owing in part to exposure to parasitic infections and in part to changes in food and climate. Even if the individual is fortunate in escaping malaria and amebic dysentery, the infective-stage eggs of *Ascaris* and the whipworm (*Trichuris trichiura*) are from time to time ingested in food contaminated by gardeners or servants. Moreover, an enervating climate usually predisposes to less exercise and the diet is almost invariably poor in green vegetables. These environmental conditions and personal habits greatly reduce resistance to disease.

Ascariasis seldom produces a severe anemia and whipworm infection in the United States is rarely heavy enough to alter the blood picture materially. However, a heavy whipworm burden may produce an anemia clinically resembling severe hookworm disease (i. e. with pronounced microcytic hypochromic anemia). The anemia of the patient under consideration is probably caused, at least in part, by a heavy whipworm infection.

Treatment of the patient may consist first of all in combating the anemia by blood transfusions, by feeding iron daily for a period of at least two weeks and by instituting a diet rich in animal proteins and vitamins. *Ascaris* can be safely eliminated by prescribing hexylresorcinol pills. This anthelmintic is administered in a single dose of 1 Gm. (five 0.2 Gm. pills) given in the morning on an empty stomach. Food is withheld for four hours. Two hours after the drug is taken it should be followed by mild saline catharsis to eliminate dead and dying worms and prevent absorption of their toxins into the system. There is no eminently satisfactory preparation available in the United States for removal of whipworms from the bowel, although several courses of treatment with combined carbon tetrachloride and oil of chenopodium (adult dose 2.7 cc. of carbon tetrachloride and 0.3 cc. of oil of chenopodium taken in the morning on an empty stomach after sodium sulfate purgation the night before and followed in two hours with sodium sulfate purgation) will probably remove most of the whipworms. However, this anthelmintic procedure should be reserved, if possible, until after the birth of the baby, since both drugs are relatively toxic and for safety require rather drastic pretreatment and posttreatment saline purgation.

TOXICITY OF NICKEL CARBONYL

To the Editor:—Please furnish me with any information you have on the toxicity of nickel carbonyl at various temperatures. Would a mask serve to protect an individual who handled this chemical?

B. H. Carlton, M.D., Port Sulphur, La.

ANSWER.—Nickel carbonyl, $\text{Ni}(\text{CO})_4$, prepared by passing a current of carbon monoxide over finely divided metallic nickel, is a gaseous liquid with a boiling point of 44 C. Reports of intoxication with nickel carbonyl have been of rare occurrence, although the poisonous properties of this substance present a constant hazard in its study or industrial application, as in the Mond process for obtaining pure nickel. Following inhalation of nickel carbonyl there is transient malaise, with quick recovery in fresh air; but after from twelve to twenty-six hours the

patient becomes dyspneic, cyanotic, febrile and delirious, with a blood stained sputum. Death occurs in from four to eleven days with hemorrhages in the lungs and brain, and pulmonary edema. Nickel carbonyl decomposes to form metallic nickel and carbon monoxide. Although nickel carbonyl is about five times as toxic as carbon monoxide, the nickel is said to be the toxic element because the amount of carbon monoxide liberated from a minimum lethal dose of nickel carbonyl is well below the lethal level for carbon monoxide. From early studies McKendrick and Snodgrass (*Proc. Phil. Soc. Glasgow* 22:204, 1890-1891) concluded that 0.5 per cent of nickel carbonyl vapor was necessary to make the air dangerous. Haldane (*J. Physiol.* 18:430, 1895), however, indicated that as little as 0.05 per cent produces symptoms even during rest. References to variation of the toxicity of this substance with change of temperature do not appear in the literature. As a preventive measure, workers engaged in processes which result in their exposure to fumes bearing nickel carbonyl should be protected by supplied-air respirators. The determination of the quantity of nickel carbonyl present in the atmosphere may be made by aspirating a known volume of filtered air through aqua regia and subsequently determining the amount of nickel salts present in the solution. Recent articles which summarize the symptoms, treatment and prevention of nickel carbonyl poisoning are the following:

MYOTONIA CONGENITA

To the Editor:—A white youth aged 17 complains of being "muscle bound." Since early childhood his parents have observed that after he has run a few steps with apparent ease his thigh and leg muscles will all suddenly seem to become tense and the extremities can no longer be moved except with deliberate effort and then at a retarded rate of speed. After a few seconds rest the musculature usually seems to relax and he can run a few steps further with normal facility of motion only to "tighten up" again. As a consequence he has never been able to run as fast as a normal individual. Endurance and strength are excellent as long as he moves at a measured pace. He has become an expert golfer and can swim or walk at slow speeds for long distances. He is unable to play games that require running or sustained rapidity of motion. He was a second child born after an uneventful pregnancy. There was no evidence of birth injury. There are two other children, both normal. There is no similar known neuromuscular dysfunctional state in the family. The boy is blond, robust and sthenic with excellent posture, carriage and a normal walking gait. He is 69 inches (175 cm.) tall, and weighs 145 pounds (66 Kg). To outward appearance his musculature and development are perfectly normal. Complete physical examination is essentially normal. No neurologic abnormalities are found. Cardiovascular studies all are essentially normal. The urine, feces, blood picture and blood Kahn reaction are negative. During test exercises the circumference of the extremity under observation will decrease by three-fourths inch at the time the increased muscle tension of both flexor and extensor groups develops. It is then that both flexors and extensors show more or less tonic contraction and are quite tense. After a few seconds rest the musculature relaxes. I should like advice as to further steps necessary in a diagnostic study. What are the diagnosis, prognosis and treatment if any? M.D., Philippine Islands.

ANSWER.—The history, as given, is entirely consistent with a diagnosis of myotonia congenita, or Thomsen's disease. There are two distinct features of the disease, as emphasized by Thomsen in his original description. As he was a sufferer himself from myotonia, one is entirely justified in using his name with the disease. The first and most constant symptom is the myotonia, or tonic, painless spasm of various voluntary muscles. It may come on after rest, so that a patient finds difficulty in getting out of bed or a chair and walking. After a slow period of warming up, movement may be normal. A second form of the myotonia is the tonic spasm of the muscles after exercise. The muscles are often so set that relaxation is markedly retarded. Patients may become immobilized in a muscle-bound state and fall to the ground *en bloc*. Rarely, however, does the myotonia reach such proportions, and most patients are simply slowed up and prevented from exerting any movement speedily. The thigh muscles are most commonly involved, and inability to run is the most frequent symptom. Endurance and strength are unimpaired; most patients have a fine muscular physique. Symptoms date back to infancy, as this is a congenital disease.

The second primary characteristic of myotonia congenita is the hereditary aspect of the disease. Thomsen described four generations in his own family, and his great-nephew Nissen has carried the record, with thirty-five cases, through three more. Atypical examples, such as the one here described, are rare and Nissen believes that adequate search would always reveal the hereditary strain. Single and sporadic cases, however, have been described and this boy may represent one of them. The

disease has been reported from various parts of the world and in diverse racial stocks.

The physical and neurologic examinations give normal results except for the myotonic reactions. A tap on a muscle is at once followed by a slow, localized contraction, causing a depression in the skin for a number of seconds. Repeated taps require longer and longer periods for relaxation. Electrical stimulation by faradism also gives the prolonged contraction.

Myotonia is present also in dystrophia myotonica, but the stringy atrophic muscles, cataracts and glandular disturbances serve to differentiate this form of dystrophy from myotonia congenita.

The prognosis for life is good; for the disease, grave. In no case is recovery known to have occurred.

Treatment, up to recent times, has been unavailing. Thomsen's recommendation of physical therapy failed to help Nissen, who gave it a thorough trial. In 1936 Wolf found that quinine abolishes the myotonia of myotonia congenita as well as of dystrophia myotonica. The action appears to be exactly opposite to that of prostigmine, a derivative of physostigmine and a pharmacologic antagonist to quinine. Wolf found, moreover, that prostigmine increases the myotonia. The opposite effect of these two drugs, incidentally, is produced in the disease myasthenia gravis, in which there is a condition of lessened muscle tonus, in the clinical sense, and easy fatigue of muscular action. The work of Wolf was confirmed by subsequent studies by Kennedy and Wolf. They recommend a dose of quinine hydrochloride of $2\frac{1}{2}$ to 5, 10 or 15 grains (0.16 to 0.32, 0.64 or 0.96 Gm.) two or three times a day by mouth. Any form of quinine may be used; for example, hydrochloride, sulfate, bisulfate or hydrobromide. Kennedy and Wolf, however, found the hydrochloride the most soluble and quickly absorbed, without disturbing gastrointestinal effects. For effective treatment a constant level of quinine in the blood should be maintained. Cinchonism, as evidenced by tinnitus, calls for a reduction or temporary abandonment of the drug. Doses of 5 grains (0.32 Gm.) three times a day are usually well tolerated and prove to be adequate for an adult to eliminate the symptom of myotonia.

ACID ASH DIET AND URINARY CALCULI

To the Editor:—If a patient has had a nephrectomy because of too massive involvement of the kidney by numerous large calcium phosphate calculi, would giving diluted hydrochloric acid, much as we do when babies have strong alkaline urines but in much larger quantities, acidify the urine sufficiently so that a continued acid ash diet will no longer be necessary? Those foods, such as milk, necessary to make my patient regain weight are forbidden because they are urinary alkalisers. Is there any possibility of injuring or altering the function of a normal stomach by the continued use of large doses of diluted hydrochloric acid, say from 30 to 60 minims well diluted per meal? Of course the phosphate and calcium foods will be restricted as much as possible. Giving small doses of insulin daily has brought slow gain because the present diet is so limited in variety.

H. R. Gutmaker, M.D., Philadelphia.

ANSWER.—After one kidney has been removed because of extensive nephrolithiasis, calculi seldom will form subsequently in the remaining kidney. With this margin of safety it is hardly necessary to use such drastic prophylactic measures as might be employed in cases with repeatedly recurring renal calculi. Although it is true that the probability of further stone formation can be reduced by dietary acidification of the urine and by reduction in calcium and phosphatic intake, nevertheless such measures are not always successful. The high acid ash diet is probably the best way of maintaining the acidity of the urine over a long period of time. There may be some difficulty in combining this diet with food ingredients low in calcium and phosphate, but it can be done. There is no reason why the high acid ash diet could not be modified so that it has a caloric intake sufficient to be nutritive. In some cases the high acid ash diet becomes burdensome and urinary acidification may be accomplished just as well by giving the patient enteric coated tablets of ammonium nitrate, 1 Gm. four times a day. Such urinary acidification should be sufficient for prophylaxis if it is

maintained in alternate weeks. Hydrochloric acid is less efficacious in acidifying the urine than is either ammonium nitrate or ammonium chloride. Although alimentary disturbance usually does not result from continuous large doses of hydrochloric acid, it causes gastric irritation in some cases. If the patient is below normal weight there would be no objection to stopping all medication and giving a high nutritive diet over a period of several weeks and then instituting an acidifying dietary regimen or the medication which may seem desirable.

SYPHILITIC CHORIORETINITIS AND PREGNANCY

To the Editor:—A woman aged 25 was diagnosed as having a bilateral chorioretinitis in August 1937. At that time she had a four plus Wassermann reaction and was advised against taking any arsenic preparation because of danger of optic nerve neuritis and atrophy. She was given a bismuth compound each week for fifty-two weeks. She is now apparently three months pregnant and still has a four plus Wassermann reaction. What should be done to prevent congenital syphilis in the unborn child? Would the use of mapharsen be acceptable in a case of this kind?

James B. Maple, M.D., Sullivan, Ind.

ANSWER.—It is not stated whether the patient has congenital or acquired syphilis. This would make a great deal of difference. The present condition of the eyes would also affect treatment. If the patient has acquired syphilis she may be given an intramuscular injection of aqueous solution of sodium bismuth tartrate 2 cc. of the 3 per cent solution twice a week for four weeks and then started on mapharsen intravenously, using 20 mg. the first dose, four days thereafter 30 mg., and if she stands it all right, 40 mg. thereafter once a week for a series of twelve injections. This should be followed with not more than five or six weekly injections of bismuth subsalicylate injections intramuscularly, and finally mapharsen. If the patient has congenital syphilis, one need not worry too much about transfer to the next generation. Third generation syphilis is rare. Nevertheless there would be no harm in giving a few injections of a bismuth compound to be followed by a course of ten arsenical injections and then in turn by a course of bismuth preparations.

BRONCHIAL ASTHMA AND CANAL ZONE

To the Editor:—Is the Canal Zone generally thought to be a good or a poor location for a patient with bronchial asthma? Such a patient contemplates accepting an attractive position there. His condition has been present since childhood. He has learned many of his allergic complexes and responds nicely to desensitization for ragweed. The patient has not been found sensitive to many foods. Sudden changes of temperature are of course a definite problem.

M.D., Illinois.

ANSWER.—The patient may be assured that he will not encounter ragweed pollen in the Canal Zone. While no local studies of atmospheric allergens have been reported for this particular area, all existing reports of similar areas indicate an absence of grasses, weeds and trees of the type found in the United States.

The temperature in the Canal Zone (Ancon) fluctuates little. The Weather Bureau reports the monthly average temperature throughout the year as varying only 1 or 2 degrees from 80 F. The average maximum is 90 F. and the average minimum 72 F. All-time records for maximum temperature are 97 F., for minimum temperature 63 F.

However, if the patient is known to respond adversely to high humidity he will have difficulty in the Canal Zone, where rainfall varies from 70 to 129 inches a year and where the average humidity varies from 77 per cent in January to 87 per cent in June.

ROENTGEN THERAPY AND PITUITARY DAMAGE

To the Editor:—Is there any reason to believe that the usual doses of x-rays commonly used in the treatment of sinus disease in children may provoke any damage to the pituitary gland? Are there any such cases on record?

Frederick H. Von Hofe, M.D., East Orange, N. J.

ANSWER.—As far as can be determined there is no reason to believe that the usual doses of x-rays commonly used in the treatment of sinus disease in children can provoke damage to the pituitary gland.

The dosage used in such cases is not high and the pituitary gland is said to be resistant to x-rays. It is an ordinary observation that in the roentgen treatment of carcinoma of the nasopharynx the dosage is much higher than that used in treating sinus disease. Yet apparent damage is not provoked in the sinusophysis if the customary precautions are employed. It seems almost needless to say that in all roentgen therapy special sense organs such as the eyes and other important ones like the thyroid and pituitary glands should be protected as much as possible.

FILIPINO-WHITE CROSSES

To the Editor:—A white woman who is married to a man whose father is a Filipino and whose mother is of white stock consulted me as to the advisability of having children. She fears the possibility of an offspring with decided Filipino characteristics. Could you send me information regarding this case and would it be possible for you to include information on literature to which I may refer?

M.D., California.

ANSWER.—The offspring is not likely to have any more pronounced Filipino characteristics than does the father—in other words, there will be no tendency to “throw back” to a more remote forebear. The child would probably be somewhat intermediate between the father and the mother unless the father has more pronounced Mongolian characteristics than are usual. There are no adequate studies of Filipino-white crosses, but general discussions of the subject may be found in:

Gates, R. Ruggles: *Heredity in Man*, New York, Macmillan Company, 1930.

OXALIC ACID AND GANGRENE

To the Editor:—About one month ago a man complained of severe pain in the tips of three fingers of the right hand and in four of the left. Nothing could be seen or palpated except for a slight grayish discoloration of the skin of the involved digits. The patient's fingers had been in contact with a rug cleaning solution for two hours. The solution consisted of acetic acid, oxalic acid and glycerin. The pain became so severe a few hours following his visit that hospitalization was necessary. The areas mentioned soon became dark and then gangrenous. All the fingertips became infected, which required incision and drainage. The fingers of the left hand healed completely. The thumb and index finger of the right hand remained definitely dry and gangrenous. Surgical intervention was necessary. An exploratory incision revealed that the tissues for about 1 cm. from the gangrenous areas were gray and devitalized. The periosteum of both distal phalanges also was involved. Disarticulation at the first joint was necessary. The blood chemistry, blood Wassermann reaction and urinalysis were negative. I am particularly interested in determining whether the solution used by the patient was responsible for the condition.

M.D., New York.

ANSWER.—This case seems to be similar to that reported by Max Grolnick (Early Gangrene Due to Oxalic Acid Immersion, *New York State J. Med.* 29:1461 [Dec.] 1929), as occurring in a painter who had been scraping floors with a solution containing oxalic acid and who developed gangrene of the hands. Schwartz and Tulipan, in *A Text-Book of Occupational Diseases of the Skin* (Philadelphia, Lea & Febiger, 1939, pp. 109, 241, 543 and 713) and White in the *Dermatogoses, or Occupational Affections of the Skin* (ed. 4, London, H. K. Lewis & Co., 1934, p. 129) both state that oxalic acid is a skin irritant.

Neither oxalic acid nor glycerin has been reported to cause such lesions, but Schwartz and Tulipan (p. 106) report a somewhat similar condition from hydrofluoric acid. In view of these facts there is a strong possibility that the solution used by the patient was responsible for the condition.

LOCAL ANESTHESIA IN INFECTED AREA

To the Editor:—A blister on the anterior surface of the middle phalanx of the index finger resulted in a deep infection. A local anesthetic was injected directly into the sore before incision. Little pus ever drained from the incision but the front of the finger became gangrenous and sloughed away, leaving a bad scar and a stiff finger. Is it good practice to inject a local anesthetic directly into a finger infection for surgery? Is nerve block considered safe in treating finger infections?

M.D., Nebraska.

ANSWER.—It is generally regarded as poor practice to inject a local anesthetic directly into an infected area, particularly a finger, in preparation for a surgical therapy. General anesthesia is preferable. However, there is some weight of authority on the other side of this question. Ludwig Adam (*Surg., Gynec. & Obst.* 60:675 [March] 1935) says “I never have been restrained by inflamed tissues from operating under local anesthesia and I never saw any unfortunate consequence. Of course, if the field is of small size, I prefer circular infiltration in the healthy tissues, or I perform block anesthesia, if feasible; but if it seems necessary, I do not refrain from infiltrating the inflamed tissue. In such cases I use a very fine needle and I inject the solution at a slow rate. I do not enter healthy regions from inflamed ones. In my experience, infiltration of inflamed tissue never caused spreading of the infection; it has rather tended toward quicker amelioration or even subsidence of the inflammation, possibly by abolishing pain.” Wolfsohn (*Chirurg* 4:851 [Nov. 1] 1932) says “The fear most surgeons have of using local anesthesia in the vicinity of furuncles and abscesses does not appear to be well founded.”

A nerve block is less hazardous than infiltration of the inflamed area but is more hazardous than a general anesthesia provided

the latter is given by an expert. It would seem that the safest rule is never to inject local anesthesia into an inflamed area, and to use nerve blocks only when general anesthesia is dangerous or unavailable.

VITAMINS AND ENDOCRINES IN DEAFNESS AND TINNITUS

To the Editor:—I would appreciate an opinion on the value of vitamin E in the treatment of deafness and tinnitus. Dr. Emmanuel Josephson of New York has written newspaper articles on this subject. I have also read of the use of progesterone in the treatment of these conditions. If they have any therapeutic value worth trying I should like an opinion as to dosage, frequency of administration and preparations to use.

M.D., New York.

ANSWER.—There is but little information on the value of vitamin E in the treatment of deafness and tinnitus. A search of the *Quarterly Cumulative Index Medicus* reveals no article germane to the subject.

Tom Spies in *Science* (91:10 [May 31, supp.] 1940) mentions vitamin E as being useful in the treatment of a number of diseases and complaints, among them tinnitus. This should not apply to the ordinary type of case, since Spies was investigating obviously malnourished persons.

There have been some reports on the value of progesterone in the treatment of deafness. Similar claims have been made for other endocrine products, but most of them are not convincing. The claims for any one endocrine product appear to be as enthusiastically supported as any other one; most of the reports pay little attention either to the type of deafness or to the site of the lesion in the auditory apparatus. Lastly, there is a paucity of careful audiometric testing.

In general it may be said that such remedies have as yet no proved value. One must guard against the too eager acceptance of therapeutic claims for the treatment of obscure and stubborn maladies at a time such as this when vitamin and endocrine therapy are undergoing a testing period, and great caution should be exercised in drawing conclusions in the absence of any but the most accurately substantiated results.

FINE VENOCAPILLARY DILATATIONS

To the Editor:—A woman aged 37 has worked as a saleslady for several years, thereby necessitating standing for long hours. She has developed varicose veins in both legs to a mild degree, only two varices being palpable, one in each leg. Her chief complaint, however, is the presence of two moderately large areas of the so-called sky-rocket or spider varices. She desires their removal because of cosmetic reasons. These two areas are proximal to the palpable varices and injection of the latter has had no effect on the former. Is there any method by which these unsightly areas can be removed without considerable possibility of scarring?

Herbert R. Atherton, M.D., University City, Mo.

ANSWER.—Spiderbursts are difficult to treat and cause little trouble. They usually occur in women at the menopause but sometimes earlier and may or may not be associated with varicosities of the saphenous system. Occasionally the fine venocapillary dilatations converge toward a central pool, which may be entered with a fine needle and injected with a mildly irritating solution such as 50 per cent dextrose or 10 per cent sodium chloride. Other patterns, however, which show parallel streaks can only be injected individually with the aid of strong illumination, a powerful binocular loupe and extremely fine needles. The technic has been described by Biegeleisen (*THE JOURNAL*, June 23, 1934, p. 2092). The method is safe in experienced hands but is painstaking and certainly does not prevent the appearance of other spiderbursts. The patients are often dissatisfied.

AGGLUTINATION WITH DYSENTERY BACILLUS

To the Editor:—A married woman aged 29 has lived her entire life in northern Minnesota, with no history of any severe illnesses and no symptoms of dysentery. What is the significance of the report that “agglutination was a typical 1:160 with dysentery bacilli, Flexner type. . . . Agglutination was absent with typhoid, paratyphoid B bacilli, *Brucella melitensis* (abortus) and *Bacterium tularensis* antigens. . . . Dysentery agglutinins may be present without any particular significance?”

I. H. Kiesling, M.D., Nashauk, Minn.

ANSWER.—A patient who has an agglutination which was typical for 1:160 with dysentery bacilli of the Flexner type has had a previous bacillary dysentery infection, and while the agglutinins may be of no particular significance in the case in question it does not mean that the patient may not later have a diarrhea which may be of bacillary dysentery origin.

AMERICAN BOARD AND SYMPOLOGY: *Oral*. Chicago, Dec. 6-7. A must be on file not later than Nov. 1. Sec., I. Marlboro St., Boston.

AMERICAN BOARD OF INTERNAL MEDICINE: *Written*. Parts I-A and I-B. Feb. 17. Final date for filing application is Jan. 1. Sec., Dr. William S. Middleton, 1301 University Ave., Madison, Wis.

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY: Part II, Groups A and B. Cleveland, Ohio, June 1941, immediately prior to opening of A. M. A. meeting. Sec., Dr. Paul Titus, 1015 Highland Bldg., Pittsburgh.

AMERICAN BOARD OF OPHTHALMOLOGY: *Oral*. Cleveland, May or June. *Written*. Various centers, March 8. The only written examination during 1941. Applications must be on file not later than Dec. 1. Sec., Dr. John Green, 6830 Waterman Ave., St. Louis.

AMERICAN BOARD OF ORTHOPAEDIC SURGERY: *Oral and written*. New Orleans, January 1941. Final date for filing application is November 15. Sec., Dr. Fremont A. Chandler, 6 N.

AMERICAN BOARD OF PEDIATRICS: Following the Region I meeting of the American Academy of Pediatrics, Chicago, May 18, following the Region III meeting of the American Academy of Pediatrics. Sec., Dr. C. A. Aldrich, 723 Elm St., Winnetka, Ill.

Colorado July Report

Dr. Harvey W. Snyder, secretary, Colorado State Board of Medical Examiners, reports the written examination for medical licensure held at Denver, July 3-6, 1940. The examination covered eight subjects and included ninety questions. An average of 75 per cent was required to pass. Sixteen candidates were examined, thirteen of whom passed and three failed. Ten physicians were licensed by endorsement to practice medicine. The following schools were represented:

School	PASSED	Year Grad.	Per Cent
Indiana University School of Medicine.....	(1939)	84	
Osteopaths *.....	77, 78, 78, 78.5, 79, 79, 80, 80, 82, 82, 82, 85

* Examined in medicine and surgery.

Louisiana June Report

Dr. Roy B. Harrison, secretary, Louisiana State Board of Medical Examiners, reports the written examination for medical licensure held at New Orleans, June 6-8, 1940. The examination covered twelve subjects and included 100 questions. An average of 75 per cent was required to pass. One hundred and thirty-three candidates were examined, 132 of whom passed and one failed. Six physicians were licensed by reciprocity to practice medicine. The following schools were represented:

School	PASSED	Year Grad.	Per Cent
Rush Medical College.....	(1939)	86.7

Book Notices

Annual Review of Biochemistry. James Murray Luck, Editor. James H. C. Smith, Associate Editor. Volume IX. Cloth. Price, \$5. Pp. 744. Stanford University: Annual Reviews, Inc., 1940.

This book, like its companion volumes that have appeared annually since 1932, is indispensable for those who wish to obtain a reading acquaintance with the present status of certain topics in the biochemical field. The present volume contains twenty-six articles by experts in different countries. Much attention is given to the enzymes, which is proper because of the growing knowledge of the importance of enzymes in the mechanism of biochemical processes. There are reviews on biologic oxidations and reductions, proteolytic enzymes and nonproteolytic enzymes. The subjects of other reviews are the biochemistry of carbohydrates and glycosides, the acyclic constituents of natural fats and oils, the lipids, sterols, amino acids and proteins and compounds of sulfur. The subjects of the metabolism of fat, carbohydrate, protein and amino acids are also included. Of special medical interest is a review of clinical applications of biochemistry. Vitamins, hormones, plant pigments, viruses and the organic acids of plants are discussed in separate reviews. There is an excellent article on the biochemistry of malignant tissue. Aspects of inorganic metabolism in plants, soil microbiology, insect biochemistry and the application of radioactive indicators in biology testify to the broad range of subjects which are covered by this volume. An article on the application of microchemistry to biochemical analysis contains brief but critical appraisals of newer methods of chemical laboratory methods. It should be read by every one interested in biochemical research.

It is not possible in a book review to do justice to the material contained in the volume. All that can be done is to list the subjects that are covered and to express appreciation of the services the reviewers have rendered in bringing together the recent literature on their respective subjects. Some of the articles will be out of date, as necessarily any review article must be, to the active investigator in a particular field. Other articles in foreign fields may be so complex that it will not be possible to gain any real knowledge of the subject from studying the review, which, being limited to recent developments, particularly those in 1939 up to November or December as some of the authors have stated, is lacking in the fundamental background of the subject. There still occur a few instances in which a reviewer simply states that a certain subject has been studied and then gives a reference to the original article and no more. This does not help much in forming an opinion about what has been done. A review should provide a critical interpretation of the reports which are cited. The mere fact that a certain subject has been studied can be ascertained by consulting the various abstract or bibliographic journals. Possibly the listing of work that has been done is an attempt to be complete by giving references to all the papers that have been published and still remain within the limits of available space. This is enough material for interesting and informative reading for many days. The book can be highly recommended as an authoritative treatise on recent developments in biochemistry.

Neurology. By S. A. Kinnier Wilson, M.A., M.D., D.Sc. Edited by A. Nislan Bruce, F.R.C.P., D.Sc., M.D., Consulting Physician Bangour Mental Hospital and St. Andrew's Hospital, Stretches. Volumes I and II. Cloth. Price, \$21, per set. Pp. 751, 753-1838, with 347 illustrations. Baltimore: William Wood & Company, 1940.

It is most regrettable that the late Kinnier Wilson's untimely death denied him the opportunity to know and enjoy the enthusiastic worldwide reception which these two remarkable volumes are receiving and justly will continue to receive. The medical world will ever be deeply indebted to Dr. Bruce for having seen to the publication of the manuscript, which at the time of Dr. Wilson's death had not yet reached the hands of the publishers.

This work is a textbook on clinical neurology. It is an excellent and timely successor to the much earlier works of a similar type by Gowers and by Oppenheim. Nor do the present volumes suffer in any respect by comparison with their predecessors. Wilson is concerned here primarily with the description, diagnosis and elucidation of nervous diseases. To this end he has drawn on an unusually full and varied experience, to which he has added probably the most complete survey of the relevant literature to be found in any book or books dealing with neurology. One would err, however, were one to assume that this work is simply a digest of literature. Wilson's patients, observations, ideas, idiosyncrasies and theories constitute the bulk of the material presented. To those of us who knew him these volumes are the essence of Kinnier Wilson. Here to an unusual extent there has been caught by unexciting ink and paper the spirit of a great man. Although it is true that each page is colored by the personal bias of Wilson, few could wish it to be otherwise. There is ample evidence of his love for coining new words and of his affection for the use of foreign words and phrases, which are liberally scattered throughout the text. There is also much typical wilsonian fencing with words, particularly terminology. His intolerance with the unproved and often illogical conclusions of others he does not always find possible to extend to his own dogmatism. Such coloring, however, is the watermark of authenticity, the incontrovertible evidence that these volumes represent the original manuscript.

There are certain sections which merit especial commendation, particularly those on disseminated (multiple) sclerosis, neurosyphilis and the epilepsies. The extensive review of the literature and the full index of authors are most exceptional and useful. It is unfortunate, however, that the bibliographic references assembled in most abbreviated style at the foot of each page are not more readily available. The arrangement of these references in complete form at the end of the last volume would be a most useful though tedious labor for which the neurologic world would be deeply indebted. It would also be advantageous to differentiate in the index of authors between different authors with the same surname. The subject index is incomplete, and not a few subjects discussed in the text are missing from the index. A few others appear to have escaped both.

In places the author has been uncritical as regards therapeutics. In the discussion of the treatment of disseminated sclerosis some twenty odd agents are presented with little or no evaluation of their true worth. There are other less glaring examples of the same fault.

Some subjects which one expects to find discussed in a textbook of this sort are missing. Most notable of these is the lack of any statement as to the symptoms peculiar to the occlusion of the principal arteries of the brain which are commonly so involved, such as the middle cerebral, the anterior cerebral and the postero-inferior cerebellar. Also certain recent advances in neurology escaped inclusion by the author or the editor. Thus hyperinsulinism and its relation to various paroxysmal neurologic disorders, carotid sinus hyperirritability, potassium deficiency in the production of family periodic paralysis and potassium salts in the treatment of that condition, and quinine in the treatment of Thomsen's disease are either not discussed or are dismissed with inadequate consideration.

That Kinnier Wilson for almost his entire life had little or no contact with modern neurologic surgery is responsible for his failure to appreciate in large measure what this special form of therapy has to offer many sufferers from neurologic disease. In this connection it is enlightening to note that when (p. 1148) he wishes to refer the reader to a textbook on neurosurgery

he refers to one English book of 1907, one French book of 1913 and three German books dated 1901, 1930 and 1930.

The presentation of subdural hematoma and of meningeal hemorrhage in general is confusing and not in keeping with modern experience and thought. The presentation of the symptoms of intracranial neoplasm (pp. 1221-1252) leaves something to be desired. The statements relative to the function of the pars intermedia and pars neuralis of the hypophysis (p. 1252) and the relations of these structures to clinical disease (p. 1244, p. 1259, pp. 1262-1264) are unsupportable. The statement on page 1276 that neurosyphilis can cause no difficulty in the differential diagnosis of intracranial tumor because "the spirochaete cannot hide its trail from the laboratory expert" evidences far greater confidence in laboratory techniques than one has come to expect from English clinicians, and one in this instance not quite fully justified. The discussion of spina bifida occulta (pp. 1417-1422) is inadequate and misleading.

Although this book has faults, as what one does not, of which the ones mentioned are representative if not all inclusive examples, they are not sufficient to detract from the true worth of these volumes. No one interested in the nervous system can afford to be without Wilson's Neurology.

Vitamin E: A Symposium Held Under the Auspices of The Food Group (Nutrition Panel) of the Society of Chemical Industry on Saturday, 22nd April, 1939 at the School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1, England. Cloth. Price, \$2. Pp. 88. New York: Chemical Publishing Co., Inc., 1940.

This monograph is a well presented discussion of vitamin E, its chemistry and physiology and its possible clinical and veterinary uses. The chemistry of vitamin E has been well worked out and synthetic tocopherol now is commercially available. Chemical tests for tocopherol in biologic materials have not yet progressed to the point at which the vitamin can be determined without recourse to animal assays. The physiologic action of vitamin E and the consequences of vitamin E deficiency have been studied by many investigators with conflicting results. Professor Drummond has pointed out that, while the organic chemists have made short work of the problems handed over to them by the biochemists in connection with the elucidation of the composition of the tocopherols, the physiologists at present are confronted with a formidable list of contradictory reports. There is not yet unanimity of opinion on the fundamental question whether the vitamins of the E group are concerned with cellular processes of the animal body or are concerned only with particular organs such as the gonads or the anterior lobe of the pituitary. When it comes to the clinical field, differences of opinion are even more marked. Dr. F. J. Browne summarizes this phase of the discussion by observing that the reports appear to cancel one another out. One author claims that excellent results are obtained in the treatment of habitual abortion with vitamin E, another states that vitamin E is of no use in habitual abortion but is valuable in threatened abortion, and still another author asserts that vitamin E is useful in habitual abortion but of little value in threatened abortion. Dr. Browne concludes that he does not consider a case has yet been proved for the value of vitamin E in either condition. This monograph is valuable because of the stimulating views it provides about the problems remaining for future investigation in the vitamin E field. It is based on a symposium conducted under the auspices of the Society of Chemical Industry in London.

Lehrbuch der Bäder- und Klimahelkunde. Bearbeitet von W. Amelung et al. Herausgegeben von Professor Dr. H. Vogt, Direktor der Reichsanstalt für das deutsche Bäderwesen. Universität Breslau. In zwei Teilen. Paper. Price, 93 marks. Pp. 608; 609-1227, with 397 illustrations. Berlin: Julius Springer, 1940.

This is a two volume textbook on spa therapy and climatology. Volume I deals primarily with spas and volume II with climate and diseases. Volume I begins with a chapter on the geology and natural history of mineral waters and peloids (mud baths). This is followed by the technic of utilizing the baths, including a classification of springs, their examination and protection, and the technical aspects of handling the waters. There is extensive discussion of piping, valves, pumps, faucets and the application of various kinds of baths, such as the tub bath, the bubble bath, the douche, the hot bath and the cold bath. Preparation of moor baths is the subject of a section in chapter II. Another section is concerned with the technic of inhalation of

gases originating from natural waters and the use of such waters internally and as gargles. Chapter III is devoted to the chemistry of waters and peloids with extensive tabular data covering alkaline waters, ground waters, salt waters, calcium waters, Glauber's salt waters, bitter waters, hard waters, iron waters, arsenic waters, sulfide waters, iodine waters, radioactive, carbonated, hot, simple cold, gaseous and sea waters. The chemistry and physics of peloids is included in this chapter. Chapter IV deals with the pharmacology of the waters and peloids, with special reference to their action on the skin, the circulation and, when taken internally, the stomach, liver, kidneys and blood. This chapter follows the same general classification as the preceding one dealing with each class of waters in considerable detail.

Volume II, beginning with chapter V, deals with bioclimatology first on a worldwide basis and then with special respect to Germany. It opens with attention to general characteristics, a discussion of weather and climate on sea level, at moderate altitudes, in the lower mountains and in the high mountains. Climatologic factors, including temperature, wind, atmospheric pressure, moisture, clouds, fog, precipitation and sunlight are described. The physiology of temperature control of the body is described with special reference to energy sources, heat losses, influences of clothing, breathing and work. Descriptions are included of ventilation and electrical and magnetic manifestations in the atmosphere. The effect of climate and weather on the body as a whole and its component parts is discussed with special reference to body weight, musculature, fatty tissue, protein metabolism, acid-alkali balance, the utilization of minerals and carbohydrates and effect on breathing, circulation, general metabolism and the relationship to work and endurance. There is a chapter on "artificial climate."

Chapter VI concerns itself with balneotherapy of the several diseases, beginning with a discussion of the rationale and purpose of the so-called cures. Effects of bath and peloid therapy on various diseases are outlined, including diseases of the blood and circulatory system, rheumatic diseases, children's and women's diseases and endocrine, nervous, digestive, nephritic, blood, skin and so-called catarrhal and allergic diseases. Attention is devoted to surgical and orthopedic indications for balneotherapy. Rather excessive emphasis is placed on climatologic treatment of tuberculosis. Chapter VII is devoted to the organization and general care of patients in baths and spas with reference to general hygiene, nutrition and diet, massage, gymnastics, sport, play and psychologic factors, including music and entertainment. Chapter VIII is descriptive of German baths and spas.

This is a comprehensive, extensively documented, highly detailed discussion of the subject, coming from a land rich in natural spas and therefore greatly interested in their utilization and the study of their effects. It is well printed and extensively illustrated with photomicrographs, diagrams and photographs. Unfortunately it is bound in paper and so poorly sewed that it began to come apart even before the reviewer had finished the first chapter. At this time, when European spas are closed to Americans and a new interest in American resources in this field is becoming manifest, this book should be a valuable reference book for any one interested.

Immunotransfuzii. [By] I. S. Kogan. S predislavim V. N. Shamova. [Immunotransfusions. With preface by V. N. Shamov.] Cloth. Price, 10 rubles. Pp. 328, with 39 illustrations. Kharkov: Izdanie Ukrainskogo Instituta Eksperimentalnoy Meditsiny, 1940.

The work of Wright on therapeutic immunization opened up a new field in the application of blood transfusion. Immunotransfusion, or transfusion of blood from donors previously prepared by vaccination, has had sporadic trials but soon fell into disuse because of more or less disappointing results. The problem was complicated by a multitude of factors involving varying effects of vaccination on the donor, the immunobiologic status of the patient, its modification by the disease and, finally, the effect on it of the transfused blood. The present volume is the result of a six year study carried out by the author in the Ukrainian Institute of Experimental Medicine (direction of Professor Shamov). The effects of active antigens were studied in animal experiments. Determination of immunobiologic indexes of the blood of the recipient was made in the clinical material, comprising 127 patients and 248 transfusions. The

effect of transfusion was evaluated in each instance by the immediate effect on the general condition of the patient and the effect on the composition of the blood, on osmotic resistance of erythrocytes, on sedimentation reaction of erythrocytes, on thrombocytosis, on bone marrow, on immunobiologic indexes of the patient's blood and on reticulohistiocytosis. The author used freshly citrated blood and is at present experimenting with preserved plasma as a substitute. The volume presents a fairly complete and interesting discussion of the various views on the subject, which, together with an extensive bibliographic appendix, makes this valuable contribution the first complete treatise on the subject. The work is in Russian.

The Pineal Organ: The Comparative Anatomy of Median and Lateral Eyes, with Special Reference to the Origin of the Pineal Body; and a Description of the Human Pineal Organ Considered from the Clinical and Surgical Standpoints. By Reginald J. Gladstone, M.D., F.R.C.S., F.R.S.E., and Cecil P. G. Wakeley, D.Sc., F.R.C.S., F.R.S.E., Senior Surgeon, King's College Hospital, London. Cloth. Price, \$10. Pp. 328, with 321 illustrations. Baltimore: William Wood & Company, 1940.

It appears obvious that the greater part of this book, more than the first 400 pages, is the work of Dr. Gladstone, whereas Mr. Wakeley's contribution is to be found in the last fifty pages. The first section, concerned with comparative anatomy and embryology, is based on the hypothesis that the pineal body is the vestige of a median or parietal eye. In passing it should be noted that the proof of this hypothesis is not presented in any clear and concise form. In fact, if it is presented at all it is lost in a tremendous mass of verbiage. The first two hundred odd pages are concerned with a discussion of the lateral and median eyes and their relationships in both invertebrates and vertebrates, a large number of both being presented in great detail. The author then presents the "pineal system" of fishes, amphibians, reptiles, birds and mammals. The anatomic relationships and microscopic appearance of the human pineal body are also presented. This book represents an enormous amount of work in compiling an extensive and variegated amount of information from the literature. It would have been more appropriately entitled "Comparative Anatomy of the Median and Lateral Eyes," and as a compilation of information relative to the photoreceptive organs it may prove of value.

Sir Arthur Keith's pronouncement in the preface, "I should mislead readers were I to assure them that this book . . . reads as easily as a work of fiction" is a classic example of masterful understatement. Reading is not primarily difficult because of some new and unfamiliar terminology but because of complicated and confusing construction. The following two sentences, which form a single paragraph on page 406, are a typical though by no means the most aggravated example:

Both in the past and recently, and in addition to the work done on the nerve supply of the pineal system in fishes, amphibia and reptiles, a large amount of work has been devoted to the study of the sensory cells, nerve cells and tracts of nerve fibers belonging to the pineal system in the human subject and in various types of mammals. This has been carried out largely with the object of demonstrating an anatomical basis by which it may be presumed the pineal organ or epiphysis is capable of being influenced by afferent impulses and can function: either by means of specific hormones secreted by the pineal cells and carried to distant organs in the circulating blood or by means of efferent nerves issuing from the gland and joining the habenular ganglia and other nerve centers of the brain or the intracranial sympathetic system—exerting through these systems a direct influence on other organs, e. g., the secretory cells of the choroid plexuses, or an indirect influence on these cells, by means of vasomotor nerves regulating the circulation of blood in the vessels of the organs supplied by them.

There is also much material of questionable relevance. To select one of many instances: Chapter 25, pages 381 to 391, is entitled "The Human Pineal Organ: Development and Histogenesis." Not one word in this chapter is concerned with the development or histogenesis of the pineal body. Instead the chapter consists of a presentation of the histogenesis of the neural tube, of the development and "functions" of the ependyma, and of the development and morphology of the astrocytes, the oligodendroglia and the microglia.

The clinical sections are weak. Symptomatology is superficially presented. The surgical technic pictured and described does not accord with American methods. Most neurosurgeons will shudder at the prospect of approaching the pineal region by retracting the hemisphere laterally in the parietal region and sacrificing most if not all of the central and parietal veins and at prying the tumor from its bed with a curved dissector.

The author's conclusion that "operations for the removal of pineal tumors have become standardized; and even if the complete removal cannot be undertaken, a postoperative course of deep x-ray therapy will complete the cure, as the majority of pineal tumors are radiosensitive" is not justified by our knowledge of pineal tumors or of x-ray therapy or the author's report of nine cases, all of which ended fatally. In no instance was operation survived longer than nine months.

There is a glossary, an author index and an extensive subject index.

Virus Diseases of Man. By C. E. van Rooyen, M.D., Extra Bacteriologist to the Royal Infirmary of Edinburgh, and A. J. Rhodes, M.B., Ch.B., M.R.C.P.E. With an introduction by T. J. Mackie, Professor of Bacteriology, University of Edinburgh. Cloth. Price, \$18. Pp. 932, with 63 illustrations. New York & London: Oxford University Press, 1940.

This is the most complete monograph on the virus diseases of man that has yet appeared. It includes descriptions of the technic of virus study including microscopy, staining, filtering, centrifugation and culture. Moreover it furnishes an extraordinary monument to the rapid development of knowledge of viruses and reflects the speed with which scientific progress can outstrip formal instruction. The study of viruses and the treatment of the diseases which they cause is developing so rapidly that any book of this nature will require frequent revising for some time to come. Thus even in this new book only a single sentence is devoted to sulfanilamide in trachoma. No textbook, however, can hope to keep pace with all advances and this scarcely seems a valid criticism. The Edinburgh authors have prepared an invaluable reference book for those whose field of professional activity crosses at any point the large group of diseases caused by viruses. It may be highly recommended.

The Work of the United States Public Health Service. Federal Security Agency, United States Public Health Service. Division of Sanitary Reports and Statistics. Supplement No. 152 to the Public Health Reports. Paper. Price, 15 cents. Pp. 82, with illustrations. Washington, D. C.; Supt. of Doc., Government Printing Office, 1940.

This booklet is an outline in condensed and popular style of the material which is to be found in more comprehensive form in the Annual Report to the Security Administrator by the Surgeon General of the United States Public Health Service. It is a descriptive report of the several functions of the United States Public Health Service, including the National Institute of Health, the Division of Foreign and Insular Quarantine, the Division of Domestic Quarantine, the Division of Sanitary Reports and Statistics, the Division of Marine Hospitals and Relief, the Division of Venereal Disease, the Division of Mental Hygiene and the so-called Division of Personnel and Accounts, which is largely an administration division. The report is a condensed descriptive narrative of the work done by the Public Health Service, together with a description of its budgets and the rank, classification and salaries of its personnel. It should be interesting to physicians who may not have a very clear idea of the rather diversified functions of this service, which is the nearest approach in our government to the national health department advocated in the Platform of the American Medical Association. The booklet should also be useful to the program committees and study groups of women's clubs, university students, advanced students in civics and elementary students in public health, to say nothing of the well informed citizen who tries to keep abreast of his government in its expansion.

Khlorny obmen i sekretniya pishchevaritelnykh zhelez. [By] L. S. Lukhtsever. Pod redaktsiyei s predislavleniem M. M. Gubergritsa. [Chlorine Metabolism and Secretion of Digestive Glands.] Cloth. Price, 6 rubles, 50 kopecks. Pp. 182, with 11 illustrations. Kiev: Gosudarstvennoe Meditsinskoe Izdatelstvo USSR, 1939.

This monograph in Russian consists of three parts. In the first part the author presents an interesting discussion and review of the literature on the subject of physiology of chlorine metabolism in the human body. The second part is devoted to a discussion of the present status of our knowledge of the pathology of chlorine metabolism in the human body. Included under this heading are such items as hyperchloremia, hypochloremia and chlorides in infectious diseases, neoplasms, cardiovascular disease and diseases of the kidney. The third part deals with the clinical-experimental work carried on by the author for the past four years and devoted to the clarifying of the subject of the relationship of chlorine metabolism to the

secretory function of the digestive glands. Patients with gastric or duodenal ulcerative disease, nephritic patients and convalescents were subjected to continued drainage of the gastric, duodenal and pancreatic secretions with the aid of a thin stomach tube. The patients were kept on a salt-free diet. The drainage was maintained daily for from five to six hours for from two to four weeks. At six day intervals the potassium, calcium, phosphorus, sodium, chlorine, pancreatic ferments, residual nitrogen, total nitrogen, albumin fractions and alkali reserve were determined. Likewise estimations were made of the urinary chlorides and the chlorides of the gastric and duodenal juice. The author has found that blood chlorides maintained a constant level of concentration even after a fairly long period of deprivation of gastric or duodenal juice. As a rule the chloride concentration of the blood showed a fall in the course of the third or fourth week of drainage only to return to normal after a few days of continued drainage. The fall in blood chlorides was paralleled by its concentration in the cantharides blister fluid, the latter reflecting tissue juices. The author also found dissociation between blood chloride content and the sodium content. Potassium and calcium were uninfluenced. The alkali reserve vacillated within normal limits. Continued drainage of the gastric juices resulted in an increase of the residual nitrogen. Parallelism was not noted between the chloride content of the gastric juices and the gastric acidity. Patients with gastric-duodenal ulcerative disease, as a rule, gained from 3 to 5 Kg. in weight at the end of this regimen and were free from symptoms of hyperacidity and pain. The author sees a therapeutic possibility in connection with the influencing of the biochemical alterations in the state of the electrolytes. Removal of chlorine assists in alkalization of the organism and the creation of optimal conditions for the healing of the ulcer. The author stresses particularly the effect of this treatment on the electrolytes with the resultant stimulation of the vegetative nervous system. The patients remained in a satisfactory condition for from two to three years. Appended is an extensive bibliography. The work, although not entirely convincing, is interesting and provocative.

A Textbook of Pathology. By W. G. MacCallum, Professor of Pathology and Bacteriology, The Johns Hopkins University, Baltimore. Seventh edition. Cloth. Price, \$10. Pp. 1,302, with 697 illustrations. Philadelphia & London: W. B. Saunders Company, 1940.

This book on pathology is remarkable for its clarity of style and its illustrations, which are wonderfully adapted to the text. The illustrations, some of which are in color, are taken almost entirely from material which the author studied in the laboratory. This edition has been thoroughly revised, but the general plan of the book is the same as that of the six previous editions. The general approach to the subject is from the point of view of etiology. Pathology must serve as an accompaniment or even as a foundation for the understanding of clinical phenomena. The importance of detailed study at necropsy is emphasized. All the chapters are followed by references to the literature. The book, which is intended for beginners, has long been a favorite among students and teachers.

Practical Bedside Diagnosis and Treatment. By Henry Joachim, M.D., Chief-of-Medicine, Israel-Zion Hospital, Brooklyn. Cloth. Price, \$7.50. Pp. 828. Springfield, Illinois & Baltimore: Charles C. Thomas, 1940.

To understand this book and appreciate its value, one should first carefully read the preface. The title suggests a regular textbook of medicine, but going into its pages with usual expectations the reviewer was disappointed in their inadequacy and was somewhat dismayed at what has been given space in a well printed and well arranged volume of convenient size. It is mainly a good discourse on differential diagnosis by an able diagnostician who lists the things one must think about before closing the case. To be "practical" as the title demands ("brief" might have been better), diseases are described in contrasting symptomatology, as the author has accumulated his enormous experience. Symptoms are retailed as they "may" occur rather than what did occur in the experience of others. The repetition of this "may be present" is monotonous (twenty-five times or more on a single page) and certainly not so satisfying as a textbook which takes advantage of the experience of others, i. e. recognizes the value of clinical statistics. If the statistical method has influenced the author, he almost never quotes a figure

or a source. The preface states that the book represents the experience of one man, and the author deserves much praise for attempting to pass it on in book form to others. Beginners will not be helped greatly by the book except those whose greatest gift is memory. Mature readers will welcome the book as being better on differential diagnosis than many others but will find the want of references and complete absence of bibliography rather impractical.

A Textbook of Physiology. By William D. Zoethout, Ph.D., Professor of Physiology in the Chicago College of Dental Surgery (Loyola University), and W. W. Tuttle, Ph.D., Professor of Physiology, College of Medicine, State University of Iowa, Iowa City. Seventh edition. Cloth. Price, \$4.50. Pp. 743, with 302 illustrations. St. Louis: C. V. Mosby Company, 1940.

This edition appears two years after the preceding and occupies twenty-nine more pages, a part of which increase is due to printing in larger type the material formerly put in 8 point type. There are eleven more illustrations than in the earlier edition. The number of tables remains unchanged at thirty-six. Most of the textual matter is unchanged, but with the addition of a second author a few new paragraphs have been added and others rewritten; however, in the main, the book is not radically altered. It is still a useful textbook for elementary and intermediate students of physiology. The style is in general direct and simple. At some points a considerable biochemical background is presupposed in the reader, and elsewhere no knowledge whatever. The printing is excellent and typographic errors are few.

Sex in Marriage. By Ernest R. Groves and Gladys Hoagland Groves. Second edition. Cloth. Price, \$2. Pp. 250. New York: Emerson Books, Inc., 1940.

This book by Professor and Mrs. Groves is more or less in the nature of an extension of their series of books on family relationships, of which *Wholesome Marriage* and *Wholesome Parenthood* are previous volumes. This book deals with sex problems in marriage, taking up first the relationship of sex and happiness in marriage. This is followed by a discussion of the effect of one's background and premarital experience on one's attitude toward sex in marriage. In mentioning premarital experience the authors intend a broad reference to sex knowledge, observation and attitude rather than to actual sexual intercourse before marriage, although this naturally is included. The sex equipment, with special emphasis on the broader biologic and psychologic aspects, is described. Chapters are devoted to the beginnings of marriage, the "love art" of the husband and wife and some common sex problems of marriage. Throughout, the approach is broadly biologic and psychologic rather than narrowly anatomic and physiologic. There is no description of the sex organs and no detailed advice about so-called sex technic. A calm and objective chapter on birth control and a philosophical discussion of sex and life conclude the book. This book can be recommended by physicians to their patients with confidence. A healthy, intelligent adult, possibly suffering from sex inhibitions and maladjustments carried over from childhood, will find it sanely and constructively helpful. It is one of the better contributions to the growing and voluminous modern sex literature for lay readers.

Gross Anatomy: A Brief Systematic Presentation of the Macroscopic Structure of the Human Body. By A. Brazier Howell, Associate Professor of Anatomy, Johns Hopkins University School of Medicine, Baltimore. Cloth. Price, \$6. Pp. 403, with 56 illustrations. New York & London: D. Appleton-Century Company Incorporated, 1939.

It is interesting that a concise, time saving compendium of gross anatomy appeared from Johns Hopkins Medical School when that institution more than any other has been responsible for the progressive curtailment of time allotted to the study of gross anatomy. The language is terse and descriptive and the sentences are short and readable. Incorrect anatomic descriptions which have been carried in textbooks throughout the years have been replaced in this book by the proper descriptions. The volume is well planned, well printed and well organized. It also is clearly indexed. The schematic type of line drawing has been used throughout to good advantage. Far too few drawings, however, intersperse the text. The book is an excellent small reference work. It has a good embryologic foundation. The English equivalents of the Basle anatomical nomenclature are used throughout.

Miscellany

NORMAL LIFE AFTER REMOVAL OF RECTUM

Condensation of a paper written by a layman who has developed a technic for caring for a colostomy which enables him to carry on an active life cheerfully. This grateful patient hopes that the routine which he has developed after periods of trial and error will encourage and inspire fellow sufferers to a bright outlook on life.—ED.

A year ago I consulted a surgeon for what I believed was a slight rectal ailment. He told me that I had cancer of the rectum and that I would have to undergo an operation involving removal of the rectum and terminating of the bowel tract in a colostomy. After he explained that this would mean that, even if the operation was entirely successful, I would have no control over excretion of fecal matter, I cared little whether I survived the operation or not. Today after this ordeal I enjoy better health than ever before, and friends tell me that I have never looked so well. I am a lawyer engaged in active practice and I work hard. I eat, drink, smoke, dance, punch the bag, and I have even ridden a surf board at Waikiki Beach.

The ability to lead a normal life is due to the development by trial and error of a technic which is all but automatic. The following equipment is essential:

1. Sponge rubber kneeling pad.
2. Towel over kneeling pad.
3. Woolen sport shirt.
4. Enema bag.
5. Glass connecting tube.
6. No. 24 catheter.
7. Largest size safety pin.
8. Small bathroom stool.
9. Rubbing alcohol.
10. Small kidney basin.
11. Two Perry colostomy belts.
12. Man's wide band elastic athletic supporter.
13. Gauze pads.
14. Yellow petrolatum.
15. Small piece of oiled silk.
16. Cellucotton.

My colostomy is about three inches below the navel. I do a complete irrigation every morning immediately after breakfast. By kneeling in front of an ordinary toilet, the opening is only a few inches above the toilet, and, in that position, flushing the bowel is no inconvenience. I suggest that irrigating from the kneeling position be started as soon as possible after the operation. I kneel on a sponge rubber pad, such as is regularly used by scrub-women. It is necessary to place a towel over the pad, as otherwise the rubber will make the bare knees sore.

During the irrigation I wear a woolen top sweat shirt, such as is worn by baseball players. I cut off the bottom of the shirt front but did not cut off any part of the back.

I use an ordinary No. 24 soft rubber catheter in which, with a penknife, I made a second small hole opposite the other hole. The tip is greased with petrolatum and should be inserted about four inches; if resistance is met after the tip of the catheter is barely inserted, the pressure of the water will force sufficient distention of the bowel to enable the catheter to be inserted farther. The other end of the catheter is attached to a glass connecting tube, which in turn is attached to the tube of an enema bag, which I hang on a nail in the bathroom wall about shoulder high. Best results are obtained by filling the bag three times with warm to hot water.

Rubbing alcohol and a small size kidney basin are indispensable, because for some fifteen or twenty minutes after completing the irrigation there is the probability of further excretion. If it is necessary to walk across the room for some forgotten object, the kidney basin can be held against the abdomen. After the enema bag is emptied, I massage the abdomen because massage stimulates discharge. On finishing, I fold four or five sheets of toilet paper, sprinkle them with rubbing alcohol, and use them to clean the abdomen; the alcohol seems in some way to stimulate further discharge. Frequently, about twenty minutes after bowel activity has apparently ceased there is a second dis-

charge. As it was annoying to wait for the possible second discharge, I arranged a mirror over the toilet so that I can shave while waiting.

The entire operation consumes less than an hour. When finished, I put on my Perry colostomy belt, after lining the cap with two types of toilet paper—one fairly hard type of paper for rigidity in holding the cap in shape, and one soft type of paper for absorption of any slight mucous discharge. I have two belts, so that they can be washed at convenient intervals.

Perhaps only once in three months is there any discharge at all after the irrigation, and these occasional instances occur immediately after eating some food which stimulates intestinal activity. All my life there were a few foods, such as stewed apples and stewed prunes, that caused pronounced bowel activity. I avoid eating these few foods; otherwise my diet is unrestricted.

At first the colostomy belt was an instrument of torture. Now it is entirely free from discomfort; I am no more aware of it than the average man is aware of the belt on his trousers. I soon found, however, that this type of belt was not comfortable for sleeping or for exercising. Now when I exercise or go to bed I wear an ordinary wide elastic athletic supporter, with the pocket cut off; under the band (and over the colostomy) I place a piece of gauze one foot square crumpled to the size of a silver dollar after greasing the gauze with yellow petrolatum. Over the fluff I put about a dozen sheets of toilet paper, and over that I put oiled silk to prevent grease from soiling the supporter.

All of this equipment can be put in a small suitcase for traveling. I have made extensive trips by boat, train and plane.

A person reading my description might conclude that this is an ordeal. On the contrary, there is not the slightest trace of pain and it is no more trouble than a daily shave, except for the time consumed.

Bureau of Legal Medicine and Legislation

MEDICOLEGAL ABSTRACTS

Medical Practice Acts: Unlicensed Practice Enjoined as a Public Nuisance.—The state of New Mexico, on the relation of the appropriate district attorney, sought to enjoin the defendant, Compere, from practicing medicine without a license. The complaint alleged, in effect, that the unlicensed practice of medicine by the defendant was a public nuisance, detrimental to the public welfare and dangerous to the public health, since the defendant was so unskilful and uninformed in the practice of medicine and without moral character that his treatments endangered the lives, health and welfare of his patients and of the public in general. The trial court sustained a demurrer to the complaint and the state appealed to the Supreme Court of New Mexico.

The sustaining of the demurrer, the defendant contended, was proper in view of *State v. Johnson*, 26 N. M. 20, 188 P. 1109, 1110. In that case the state sought to enjoin Johnson from practicing osteopathy and medicine without a license, but all that was alleged in the complaint seeking that relief was that Johnson's unlicensed practice "constitutes a nuisance, and is dangerous, detrimental, and injurious to the health of the inhabitants of the county of Bernalillo and state of New Mexico." In that case the Supreme Court of New Mexico, in holding that the complaint failed to state a cause of action, said:

Our Code provides that complaints must contain "a statement of the facts constituting the cause of action, in ordinary and concise language." . . . Examining the complaint, we find but one fact stated, viz. the practice of osteopathy or medicine without a license. The allegations that such practice is a nuisance, or is detrimental, dangerous, and injurious to the public health, are merely conclusions of the pleader. Practicing osteopathy or medicine without a license is not a nuisance per se.

But, said the Supreme Court, our decision in the Johnson case is not here decisive. If the state had here alleged no more than the practice of medicine without a license and had merely pleaded the conclusion that this was dangerous and a nuisance, we believe a demurrer should be sustained. But here the state alleges much more. The complaint in this case, it is true, does allege

that the defendant is unlicensed, but it also sets forth that he "is unskilful and uninformed in the practice of medicine, and does not possess the moral and professional qualifications required" for such practice; that, because he is uninformed on the subject of medicine and because of his lack of skill and his want of moral and professional qualifications, in prescribing drugs and treating physical and mental ailments of the people he endangers the health and lives of the public. The demurrer admits the truth of these allegations. These are sufficient allegations of ultimate facts, absent in the Johnson case, "to let the complaint by the demurrer," unless in other respects the complaint in this case is bad.

Briefly summarized, the defendant contended that the present complaint is fatally defective because (a) the penal provisions of the New Mexico medical practice act afford an adequate remedy against one who practices without a license; (b) an injunction would violate his constitutional guarantee of a jury trial, and (c), even though he does all the things alleged in the complaint, such conduct on his part does not constitute a public nuisance. The court did not regard the penalty authorized by the medical practice act for unlicensed practice (a fine of not more than \$100 and/or imprisonment not to exceed ninety days) a remedy exclusive or adequate for such an offense. While power to abate a public nuisance, said the court, is "an ancient head of equity jurisdiction," there was a time when courts of equity refused to enjoin an act of criminal nature or an offense against the public, even if the act was a public nuisance, provided the act complained of did not interfere with the enjoyment of property. At this time, however, it is well established that injunctive relief may be utilized to protect the public health, morals, safety and welfare from irreparable injury by a public nuisance, and the fact that the acts constituting the nuisance are punishable criminally will not deprive equity of its power to enjoin in a proper case. Equity acts in such cases not because the acts are criminal but rather in spite of that fact. In so holding the court cited with approval *People ex rel. Bennett v. Laman*, 277 N. Y. 368, 14 N. E. (2d) 439; *Kentucky State Board of Dental Examiners v. Payne*, 213 Ky. 382, 281 S. W. 188, and *State ex rel. La Prade v. Smith*, 43 Ariz. 131, 29 P. (2d) 718, in all of which the courts enjoined as a public nuisance the unlicensed practice of a profession. Admittedly, continued the court, there are decisions to the contrary, but we prefer to follow the decisions holding equitable relief proper if facts similar to those here alleged are proved. This is not to say that in a trial on the facts the mere showing of illegal practice warrants injunction. Nevertheless, if unlicensed practice is carried on from day to day among the people generally by an unskilled and ignorant pretender who prescribes drugs, dangerous as well as harmless, and directs treatment for all manner of ills, physical or mental, to which the flesh is heir, it requires little imagination to conclude that the health and lives of the people so served and of the whole community are jeopardized. Such practice clearly falls under the definition of a public nuisance. In *Stamm v. City of Albuquerque*, 10 N. M. 491, 62 P. 973, it was taken for granted by the territorial court that anything menacing the health of the public generally was a public nuisance. Where the facts are alleged as strongly as in the instant case, it is better, we think, that the trial court hear the evidence and on it grant or deny relief than to declare as a matter of law that such conduct does not amount to a public nuisance, which we believe it does.

In the opinion of the court, the awarding of injunctive relief worked no deprivation of the defendant's constitutional guarantee of a jury trial, since the state constitutional provision concerned (Article 2, Sec. 12) merely provides that the right of trial by jury as it existed at the time of the adoption of the constitution shall be secured to all and remain inviolate, and since, because equity anciently had jurisdiction to abate a public nuisance, the defendant was not entitled to a jury in such a case as this at the time of the adoption of the constitution.

The defendant further contended that because a provision of the dental practice act requires a person to be convicted one or more times of practicing dentistry without a license before he can be enjoined from practicing without a license, the legislature evidenced a policy to deny the injunctive process against the unlawful practice of medicine. This is transparent reasoning,

answered the Supreme Court. If it is true, as we hold, that the power to abate a public nuisance is "an ancient head of equity jurisdiction," and that any practice or condition that menaces the lives, health and welfare of a considerable number of the people in a given community constitutes a public nuisance, as is now generally agreed, then it would be more correct to say that the legislature, in failing to interpose the same condition to injunctive relief against the illegal practice of medicine as it did with reference to the illegal practice of dentistry, has evinced an unmistakable purpose to leave equity courts unfettered in their power to abate as a public nuisance what is unquestionably the more dangerous practice.

The Supreme Court concluded that the trial court erred in not permitting the state to present evidence in support of the facts alleged in the complaint, which, if established, undoubtedly would present a case of a public nuisance and would authorize the issuance of an injunction. The judgment of the trial court was therefore reversed and the trial court directed to overrule the defendant's demurrer.—*State ex rel. Marron, Dist. Atty. v. Comperc (N. M.)*, 103 P. (2d) 273.

Medical Practice Act (Michigan): License Not Required to Practice Midwifery.—The medical practice act of Michigan was amended in 1913 and, after providing for the examination, regulation, licensing and registration of physicians and surgeons, provided that those "who wish to begin the practice of medicine, surgery and midwifery in any of its branches, in this state, shall make application to the board of registration in medicine, to be registered and for a certificate of registration." The defendant, a midwife qualified by education, training and practical experience and engaged solely in the practice of midwifery, had never applied for or obtained a certificate of registration. She was convicted of practicing medicine without a license in violation of the medical practice act, as amended. From that conviction she appealed to the Supreme Court of Michigan.

The amended medical practice act did not provide a penalty for the practice of midwifery apart from the practice of medicine or surgery. The defendant contended that the amended act, therefore, did not apply to a person engaged solely in the practice of midwifery, but applied only to those who wished to practice medicine, surgery and midwifery, inclusive. According to an opinion of the attorney general of Michigan, rendered in 1914, the practice of midwifery had long been recognized as separate and distinct from the practice of medicine and surgery. At that time the attorney general expressed the further opinion that, since the 1913 amendment to the medical practice act did not specifically provide for the registration of those desiring to practice midwifery only or refer to the statutes recognizing that practice, the amendment could be construed only as regulating those practicing medicine, surgery and midwifery. The Supreme Court adopted the attorney general's opinion and held that "the invoked statute does not include the practice of midwifery only," and so the defendant was not required to take the examination required of physicians and surgeons and obtain a license. The court pointed out, however, that persons who desire to practice medicine and surgery and midwifery, as components of their practice, must pass such an examination and be licensed. The judgment of conviction was therefore reversed.—*People v. Hildy (Mich.)*, 286 N. W. 819.

Malpractice: Liability of Attending Physician for Burns Sustained in Maternity Home.—The plaintiff's wife was delivered of a baby by the defendant physician at a maternity home owned by Mrs. Scoby. The baby was given to Mrs. Scoby, who was instructed by the defendant to keep it warm. She wrapped it in a rayon blanket, placed it on an overstuffed chair in the reception room on top of an electric heating pad which was connected by an electric cord to a light fixture hanging from the ceiling. About half an hour later, after attending to the mother in the delivery room, the defendant thoroughly examined the baby in the reception room and found it to be normal, but he did not see the heating pad or the cord attached to it. He then left the maternity home and returned when summoned about two hours later, at which time he found on the baby's buttocks two burns, one the size of a silver dollar

and the other the size of a half dollar. As a result of these burns it was claimed that nephritis developed, which necessitated expenditures by the plaintiff of about \$3,500 for medical and hospital services. The plaintiff later sued the defendant physician for malpractice. From the judgment of the trial court directing a verdict for the physician, the plaintiff appealed to the Supreme Court of Michigan.

Although, said the Supreme Court, the testimony of the plaintiff's witnesses was to the effect that at intervals it had been observed that the heating pad had been connected for a period of about one hour, none of these witnesses were present at the time the defendant examined the baby. It was quite possible that between such intervals Mrs. Scoby may have disconnected the electric cord prior to the physician's examination and reconnected it afterward. The defendant testified that he did not advise the use of the pad, knew nothing about it until after the burn, did not see it at the time he made his examination of the baby, and if the appliance had been connected at that time he would have noticed it and had it removed. The court considered it significant that the plaintiff had failed to call as a witness Mrs. Scoby, who was present at the time of the physician's examination, to testify whether or not at that time the heating pad was connected. In the judgment of the court, the evidence did not show that the heating pad was present under the baby and connected at the time of the defendant's examination. The majority of the court was of the further opinion that the plaintiff had also failed to prove that the defendant had been negligent in failing to observe that a heating pad was being used to keep the baby warm.

The testimony, continued the court, showed that the use of the heating pad was solely Mrs. Scoby's idea. The defendant did not instruct her to place the baby on such a pad. His only instruction was to keep the baby warm. The heating pad was placed by her under the child while the defendant was in another room attending the mother. The court concluded, therefore, that the defendant was not liable for the negligent acts performed out of his presence and without his knowledge by Mrs. Scoby, who was employed by the plaintiff and not by the defendant.

Accordingly, the Supreme Court affirmed the judgment in favor of the defendant.—*Wabeke v. Bull (Mich.)*, 286 N. W. 825.

- Western Surgical Association, Topeka, Kan., Dec. 6-7. Dr. Albert H. Montgomery, 122 South Michigan Blvd., Chicago, Secretary.

Current Medical Literature

AMERICAN

The Association library lends periodicals to members of the Association and to individual subscribers in continental United States and Canada for a period of three days. Three journals may be borrowed at a time. Periodicals are available from 1930 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 18 cents if three periodicals are requested). Periodicals published by the American Medical Association are not available for lending but can be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

Lead Poisoning in Infancy.—Bruce states that his experience at the two charity hospitals of Louisville leads him to believe that lead poisoning is not an uncommon cause of convulsions in children. Lead may be the direct as well as the indirect cause of convulsions, as a child who has suffered from lead encephalopathy will be more susceptible to convulsions when acute infections are contracted later on. Lead poisoning is possible by inhalation or ingestion. Battery boxes are a tempting source of fuel to the poor, but the smoke carries particles of lead which are easily inhaled in the poorly ventilated and over crowded dwellings. However, the commonest cause is chewing paint from furniture, toys and window sills. Drinking water may be contaminated with lead from white lead used in plumbing. Other causes may be lead nipple shields and lead-containing ointments on the breast of nursing mothers. Irritability is one of the principal clinical symptoms of lead poisoning in young children. The most constant finding is the x-ray appearance of a dense white line in the epiphyses of the long bones. Every child less than 5 years of age with convulsions, unless from an obvious cause, should have roentgenograms of these bones made. Treatment consists of removing the source of lead, except in the case of encephalopathy when sedatives are indicated, and the child permitted to delead himself slowly. This is safer than any method of deleading, which may bring the lead from the bones, where it is harmless, into the blood stream and into the nervous tissues when convulsions occur.

Rust and Smut Causing Respiratory Allergy.—Waldbott and Ascher found that certain patients with severe symptoms of asthma during July and early August were sensitive to the spores of rust and smut. Among 106 consecutive patients with asthma and nasal allergy there were seven asthmatic patients who exhibited symptoms at no other time than late July and early August, ten suffered more or less severe exacerbations of a perennial asthma during this time and two suffered similar exacerbations of nasal catarrh. The other eighty-seven patients had no symptoms at the time in question. Throughout the summer months of 1938 the patients were instructed to keep a record of the dates of their symptoms. In their daily symptom chart the severity was graded from one to four plus. Scratch and intradermal skin tests were performed for the rusts of wheat and the smuts of corn and oats. As control tests extracts from the grains, as well as of the straws of the selected rusts and smuts (wheat, oats and corn) were applied. Also the 106 patients were tested for alternaria, hormodendrum, penicillium, timothy and ragweed, as these pollen and fungi were constantly present in the air during the season in question. The straws used for extraction were examined microscopically and found free of rust and smut infection. The seven patients with symptoms only in July and early August exhibited by far the strongest reactions to the rust and smuts, whereas their reactions to pollen and the other fungi were considerably less pronounced. The twelve patients suffering exacerbations at the rust and smut season reacted less to rust and smut but gave stronger reactions to the pollens and the other fungi. The control group of eighty-seven patients gave negligible reactions to rust and smut, but those to pollens were most pronounced. The patients sensitive to smut and rust were also more sensitive to the respective cereals and their straws than were the other patients. In no case were individual reactions to the grain as strong as to the fungus. All the patients gave only minor skin reactions to the other fungi tested. Two patients were encountered in whom intradermal skin tests for rusts produced generalized reactions, even though preliminary scratch tests were carried out. Effects of hyposensitization with rust and smut extracts were very striking in some of the patients; the symptoms subsiding after two or three injections. The treatment is difficult to evaluate, as the fungus season is relatively short and spontaneous recovery may have occurred in some of the patients. The serum of the two patients with strongly positive intradermal responses to rust produced positive passive transfer reactions on normal individuals. Two cases are reported in which asthmatic symptoms were reproduced on inhalation of rust powder outside the season.

Pathogenesis of Banti's Disease.—According to Thompson, during the last ten years 137 cases of Banti's disease were seen by members of the spleen clinic at the Presbyterian Hospital. Of the 137 cases 100 have been followed for a sufficient number of years for ideal clinical investigation. The current concept of the spleen clinic is that Banti's syndrome is the result of mechanical obstruction to the flow of blood within the portal system. The site and character of the obstruction must be such that a chronic increase in splenic vein pressure occurs. At the same time the venous pressure in the peripheral circuit should be approximately normal. This differential in

pressure is, they believe, the actual cause of the splenomegaly and explains the collateral circulation. Microscopic study of sections of sixty-eight spleens from patients with congestive splenomegaly has led to the conclusion that no detectable histologic differences exist between the spleens of the various subdivisions of this syndrome. All show variable degrees of follicular atrophy, fibrosis of the pulp with dilated venous sinuses and perifollicular hemorrhages. The obstructive lesions are intrahepatic or extrahepatic. The intrahepatic lesion is cirrhosis. Hepatic cirrhosis was present as the obstructive factor in 68 per cent. The typical clinical and pathologic picture of Banti's disease develops secondary to portal hypertension. This sequence is responsible for the splenic enlargement seen in Egypt, China and the Caribbean area and due to schistosomiasis mansoni. Biliary cirrhosis and cardiac cirrhosis do not produce congestive splenomegaly. Periportal cirrhosis of the Laënnec type results in a variable degree of splenomegaly. A review of eighty-one necropsies reveals that approximately 60 per cent recorded as Laënnec cirrhosis have an associated splenomegaly of the Banti type and esophageal varices. The periportal scars are dense and there is great distortion of the intrahepatic vascular bed and minimal evidence of hepatic cell damage. Many of these patients present the clinical features of Banti's disease and many ultimately die of hemorrhage from rupture of the esophageal varices. In the remaining 40 per cent there is less connective tissue, less distortion of the vascular bed and more evidence of injury of the hepatic parenchyma and these individuals die of hepatic insufficiency with clinical cholemia. Intermediate stages exist. The degree of splenomegaly can be predicted from microscopic study of the liver. The important lesion is in the liver, and the extent, type and velocity of progress of the hepatic lesion is what determines the prognosis. If cirrhosis, as the obstructive agent, does not exist at the time of splenectomy it will not appear subsequently. Cirrhosis exists in more than half of the cases as the obstructive factor; in the remainder the obstruction to the portal flow lies elsewhere. Extrahepatic lesions responsible for congestive splenomegaly are many and varied. Thrombosis of the portal or splenic veins may occur as a result of injury or infection and Banti's disease, typical in all respects, may result. Other obstructive lesions may be cavernomatous transformation of the portal vein, compression of the splenic vein by tumors and scars and defects in the portal vein, such as anatomic developmental defect, a thrombosis occurring at the time of birth coincident with the thrombosis of the umbilical vein and stenosis. The syndrome is considered as a chronic congestive splenomegaly, a term suggested by Larrabee.

Treatment of Hypertension.—Allen and Adson state that, since hypertension is produced by increased resistance to the flow of blood through the arterioles, the specific need in medical treatment is a preparation which will restore arteriolar resistance to normal and which will not produce harmful or unpleasant side effects. Such a preparation is not available at present. Rest and the reduction of nervous stresses and strains are advisable. Young persons who follow occupations that are strenuous from a nervous standpoint may well consider it advisable to change to an occupation that is more restful. However, methods of medical treatment (diet, drugs, restriction of alcohol, curtailment of smoking and the like) available today are unsatisfactory so far as reduction of blood pressure is concerned. Sympathectomies have been performed in the hope that they may modify the mechanism by means of which blood pressure is elevated in essential hypertension. The results of operation can be predicted with reasonable certainty by observing the response of the blood pressure to rest and sleep, to the ingestion of sodium amytal and to intravenous injection of pentothal sodium. When poor results are predicted from these tests, operations are almost uniformly unfavorable. Likewise when good results are predicted some patients do not receive the anticipated benefit from operation. There were no operative deaths among a series of 300 cases. The operation itself does not disable, although anhidrosis of the lower extremities and loss of ejaculation and probably of fertility of the male patient results. Female patients have borne children subsequent to the operation. Clinical symptoms invariably disappear when the blood pressure is reduced, but a number of patients continue to

be free from symptoms even though elevated blood pressures gradually return. The results justify continuance of the operation. Individuals who will receive most benefit from surgical intervention are those who seek treatment early in the course of this progressive disease, before irreparable damage has resulted to the cardiac, renal and vascular tissues.

Diverticulitis of Colon and Surgical Complications.—Arnheim lists the following complications of diverticulitis of the colon that require surgical intervention: (1) peritonitis resulting from passage of organisms through inflamed diverticula without perforation, (2) perforation of inflamed diverticula, (3) fistula formation, (4) peridiverticulitis, (5) metastatic suppuration and (6) carcinoma arising from diverticula. A review of literature shows that surgical complications of diverticulitis of the colon occur in more than half of the cases in the following incidence: peridiverticulitis 20 per cent, abscess 19 per cent, peritonitis 12 per cent and sigmoidovesical fistula 8 per cent. From 1927 to 1937 thirty-five cases of diverticulitis of the colon were admitted to the surgical services of the Mount Sinai Hospital. Surgical complications were not present in sixteen. The incidence of surgical complications in the remaining nineteen was as follows: peritonitis without perforation in two, abscess in five, perforative peritonitis in five, stenosis (peridiverticulitis) in four, sigmoidovesical fistula in two and associated carcinoma in one. The ages of the patients in the uncomplicated group ranged from 50 to 83 years (average 69) and in the complicated ones between 18 hours and 73 years (average 51 years). The diverticulitis of the colon in the 18 hour old infant is the earliest on record. The symptoms in the uncomplicated cases were, in the order of frequency, pain in the lower part of the abdomen, constipation, diarrhea, blood in the stools and vomiting. The symptomatology in the complicated cases was determined by the type of complication present. The sigmoid was the most frequent site of the disease, though perforation of a diverticulum of the splenic flexure occurred twice. Operation was not performed in the uncomplicated cases; they subsided under conservative therapy. The operative mortality was 62 per cent. There was one death in the two cases of peritonitis without perforation. Three deaths occurred among the five cases with perforation and abscess. A gangrenous inflammation of the abdominal wound and tissues surrounding the operative site contributed to the fatal issue in one case. The two other patients were in a poor condition; drainage of their large multilocular abscesses did not influence the course of the disease. Four of the five patients with advanced diffuse peritonitis died. Two of these patients were so toxic that operation was not performed; the third death was that of the 18 hour old infant, and the

fourth patient was operated on within a few hours of admission without adequate preoperative therapy. Two deaths occurred among the four cases of peridiverticulitis. One patient had an advanced intestinal obstruction. He refused operation and died the day after admission. The other patient had a primary resection of the sigmoid with an end to end anastomosis. There was no necropsy, but clinical evidence indicated peritonitis. The two patients with sigmoidovesical fistulas died. Death in one was due to leakage of the end to end anastomosis suture line and peritonitis. The other patient had advanced perisigmoidal suppuration. The patient with associated carcinoma died of a peritonitis secondary to the perforation of the diverticula of the sigmoid.

Adenoma of Islets, Hyperinsulinism and Adenoma of Thyroid.—Greenlee and his collaborators report a case in which coexisting hyperfunction of an adenomatous goiter and an adenoma of the islets of Langerhans was corrected by appropriate operations. Biologic assays of the tumor tissue removed from the pancreas proved its insulin activity. The most important clinical feature of hyperinsulinism was that attacks of coma or unconsciousness came on when the patient had abstained from food for some time or had exercised; the coma-like episodes were relieved spectacularly by the administration of sugar. The sugar tolerance curve following operation resembles a diabetic curve. It is conceivable that the patient has a pancreatitis with disturbance in her remaining islet tissue and has a mild degree of diabetes. This would fit in well with the fact that both cholelithiasis and hepatitis were found at operation. Episodes of unconsciousness were undoubtedly of hypoglycemic origin. The patient appeared to be definitely hyperthyroid. There was nothing to prove or disprove that the thyroid disturbance was secondary to the hypoglycemia. It was felt that operation on the thyroid was indicated first because (1) any tendency to a hypoglycemic reaction following it could be controlled by dextrose and (2) there was some possibility that the patient's extreme emaciation, presumably due to hyperthyroidism, might have so lowered tissue glycogen that a hypoglycemic state resulted. A left lobectomy was performed. The pathologic report was cystic adenoma of the thyroid and hyperplasia. The patient made a satisfactory convalescence save for one spell of coma about one week postoperatively. She responded quickly to coffee and sugar. In more than a year she had had only two episodes of complete unconsciousness, but she had had several seizures which were averted by the timely administration of sugar. In view of the incomplete relief of the symptoms, the patient was readmitted to the hospital for exploration of the pancreas. A tumor about 1.5 cm. in diameter was found situated in the body of the pancreas near its junction with the tail lying close to the inferior border. The gallbladder contained stones and there was moderate hepatitis. Exploration of the rest of the upper part of the abdomen was negative and no further tumors were found in the pancreas. The patient made an uneventful convalescence save for moderate ileus for a few days. Blood sugar determinations on the third and seventeenth postoperative days were 179 mg. and 94 mg. respectively. A blood sugar determination made about five weeks after operation was 95 mg. The last blood sugar determination, April 15, 1939, was 90 mg.

Bilateral and Bilocular Empyema.—According to Ehler and Sommer, 418 patients with thoracic empyema due to pyogenic organisms following infections of the respiratory passages were admitted to the University of Michigan Hospital from 1925 to August 1938. There were twelve of bilateral empyema; three were chronic, while nine were acute at the time of admission. Four of these patients did not receive treatment, as the condition was not recognized until after they died. Of the eight treated patients with bilateral empyema, one was cured by bilateral aspiration. Three patients were treated with aspiration alone on one side and with open drainage, following aspiration, on the contralateral side. Aspiration followed by bilateral drainage was employed for one patient, three weeks intervening between the drainage operations. Prolonged aspiration was deemed unnecessary for the one chronic case; the two sides were drained two days apart following diagnostic taps. One patient, an infant of 18 months, died. The child was admitted

with bilateral empyema of four months and in extremely poor general condition. Following aspiration for two days, both sides were drained by an efficient airtight technic at one operation; the child died four days later of advanced malnutrition in spite of transfusions and other efforts to improve his condition. The eighth patient was admitted with empyema on the right side, while on the left side there was an apparently uninfected pneumothorax with multiple bronchopleural fistulas, which had developed following drainage of a previous empyema on the left side; the drainage tract was healed. Cure of the empyema on the right side followed drainage and after complete healing a left thoracotomy was performed with suture of the fistulas and airtight closure of the thoracic wall without drainage; the left lung slowly reexpanded and complete recovery ensued. No cardiac or respiratory symptoms followed open drainage with the institution of efficient airtight drainage. Among the 418 cases there were thirteen of bilocular pockets in the same pleural cavity. One of these was admitted following drainage elsewhere, one developed in the hospital, one was of three weeks duration on admission, one of one month, three of six weeks, five of four months and one of fourteen months. Only three were considered early cases. In only five cases, including three in which the diagnosis was made during operation, was it possible to institute double drainage through a single operative wound; in the remaining eight two incisions were necessary. Two patients died. The cause of one death was multiple actinomycotic liver abscesses and of the other it was osteomyelitis of the ilium. The recognition of multiple loculation depends on careful preoperative and postoperative study of postero-anterior and lateral or oblique roentgenograms whenever the condition is suspected from clinical and physical signs. The foci should be drained as they are recognized, either through the original or through supplementary incisions.

Effect of Ultraviolet Radiation on Roentgen Rays.—Ellis and Kirby-Smith believe that the former lack of adequately accurate measurements of dosage, mistakes in technic and overdosage are the main causes for roentgen ray sequelae and not a concomitant actinic dermatitis or/and a dermatitis due to external irritants. The combined application of roentgen rays and actinic rays should be repeated with all factors controlled by modern methods and standards of measuring dosage. In 1939 they examined eleven patients who had received from ten to sixteen one third erythema doses of roentgen rays and from four to twenty-one erythema doses of ultraviolet rays. All of the patients applied a two ply acne lotion to the treated areas. The time from the termination of treatment to the reexamination was from three to eight years. Nine patients have had subsequent roentgen and actinic

ray therapy. None of them showed any evidence of roentgen ray dermatitis; in fact, in half of them there was an excess of facial oil and in the majority some acne lesions still developed. The authors have replaced this routine of therapy during the last few years by a technic of giving approximately 70 roentgens weekly. They have continued to use the modified white lotion concurrently, without any evidence of roentgen ray sequelae. In their opinion the roentgen therapy has simply an additional action on actinic effect on the skin; for instance, if R represents the permanent or late roentgen ray effect and A the permanent actinic cutaneous change, then the total late changes will equal R plus A. When R and A are given simultaneously, alternately or later, neither exerts a beneficial or deleterious action on the other, but only a summation of one plus the other.

Sulfanilylguanidine for Intestinal Infections.—In a study of various sulfonamide derivatives Marshall and his colleagues found that sulfanilylguanidine is fairly water soluble but is poorly absorbed from the intestine. This makes possible a high concentration of the drug in the intestine and a low concentration in the blood and tissues, a situation somewhat analogous to the use of sulfonamide derivatives as urinary antiseptics. They present data on the preparation, structure, chemical and physical properties, pharmacology, experimental therapy and possible clinical uses of this drug. The antibacterial activity of sulfanilylguanidine suggests that it or some other derivative having similar properties may prove useful in the treatment of infections mainly or entirely localized in the intestine. From their experiments on dogs, mice and rabbits it appears that the drug given orally is no more toxic and is probably less toxic than sulfapyridine and sulfathiazole. The drug is conjugated in the mouse, rabbit and man but not in the dog. It passes into the spinal fluid much more slowly than do sulfanilamide and sulfapyridine. It rapidly penetrates the tissues with the exception of the brain. Sulfanilylguanidine is somewhat less effective against a beta-hemolytic streptococcus infection in mice than is sulfanilamide, but it is as effective as sulfapyridine against pneumococcal infection in mice. In vitro studies show that it is as or even more effective than sulfanilamide against various bacteria. The concentration of coliform bacteria in the feces of mice can be reduced by its administration. The pharmacologic properties of the drug suggest that it may prove effective in the treatment of bacterial intestinal infections in man. However, evidence of its therapeutic capabilities can be obtained only by a careful clinical study. The solubility of the drug, accompanied by its low absorption from the intestine, would appear to constitute its chief advantage over the sulfonamide derivatives in use at present. The rapid excretion of the drug is a definite advantage. Acetylation of sulfanilylguanidine is no disadvantage, since acetylation does not occur in the intestine, but probably increases the toxicity of the drug.

Ineffectiveness of Potassium Chloride in Allergy.—The remarkable results of Bloom and Abt with potassium chloride in allergic disorders prompted Furstenberg and Gay to observe its effect on eighty-five patients manifesting allergic symptoms; fifty complained of pollen hay fever, seventeen of perennial allergic rhinitis, three of rhinitis due to physical or functional factors, six of chronic angioneurotic edema and urticaria, four of eczema and five of asthma. The potassium chloride was given in tablet, powder, capsule and liquid form. Therapeutic results were not affected by the mode of administration. Several patients had epigastric pain when the salt prescribed in tablet form had not been diluted with water at the time of ingestion. The salt was given in daily doses of from 15 to

80 grains (1 to 5.2 Gm.). Most of the patients were given the medication for one week, and a few for as long as one month. Results were almost uniformly poor irrespective of the type of allergic disorder observed. The authors believe that if potassium chloride is an effective therapeutic agent in allergic diseases its best effects should be among hay fever patients who come under observation for the first time while they are suffering acute symptoms during the pollen season. However, their observation shows its failure in this group. A few patients who thought they were more comfortable after taking potassium chloride derived equal comfort when, unknown to them, sucrose was substituted. Likewise potassium chloride was of no benefit to those patients with severe symptoms of hay fever in spite of adequate preseasonal treatment with pollen extracts. Similarly, few of those patients presenting perennial allergic rhinitis showed substantial improvement. Slight improvement was noticed by two patients but psychotherapeutic factors or spontaneous changes in the natural course of the disturbance may have been responsible for the improvement. None of the patients with physical rhinitis, angioneurotic edema, urticaria or eczema derived benefit from potassium chloride. Six patients—four treated coseasonally with potassium chloride and two treated preseasonally with pollen extract and then given potassium chloride—had asthma during potassium medication. It is the authors' opinion that oral administration of potassium chloride has not proved of value in the treatment of allergic diseases.

Peroral Insulin for Diabetes.—Murlin and his co-workers studied the effect on twenty patients with diabetes of varying severity of hexylresorcinol and a buffering mixture of salts on the absorption of insulin from the alimentary tract. The "standard dose" was 100 international units of pure insulin in a solution containing 0.125 per cent hexylresorcinol and alkaline salts necessary to give a pH of approximately 10 to 10.5. As many as eight such standard doses can be given in one day without interfering with digestion, the last dose being administered not later than 11 p. m. and the twenty-four hour urine period closing at 7 a. m. Diets were kept constant for control and experimental periods. Results on urine sugar for twenty-four hours and blood sugar change early in the morning from the first dose of oral insulin of the twelve patients who reacted most favorably (four of the remaining eight did not cooperate and the conditions of the test of the other four were not unimpeachable) show weighted average effects on urine sugar varying from 4.7 to 17.7 Gm. for twenty-four hours below the average excretion in control periods. The blood sugar effect from the single dose varied from nothing to 60 mg. per hundred cubic centimeters in forty-five minutes. The total insulin for twenty-four hours varied from 200 or 300 to 800 international units. The effects on urine sugar were not proportional to the dosage, often being as great after from 200 to 300 international units as after from 600 to 800 international units. Greater effects were obtained when urine sugar and fasting blood sugar were high than when they were

low. The equivalent unitage effects of oral insulin in terms of subcutaneous (regular) insulin varied from 2.1 to 22 international units, the average of patients of whom this assay was possible being for all doses of oral insulin just below 10 international units of subcutaneous insulin. The results, the authors say, are only mildly encouraging for the hope of adequately controlling diabetes mellitus with oral insulin.

Age at Onset of Rheumatic Disease.—Gauld and Read investigated the incidence of rheumatic disease (chorea, polyarthritis and carditis) in the parents, uncles and aunts of ninety-six unselected white rheumatic children admitted to a university clinic, emphasizing the age at which the first onset of the disease was observed. Of the total number of 971 members of this generation, 132 had definite histories of the disease in some form, but only for 115 could the age of onset be definitely ascertained. The incidence of rheumatic disease was found to be greatest between the ages of 5 and 14 and 25 and 34 years. In twenty of the fifty-one persons whose onset occurred before they were 15 years of age, the first manifestation was an attack of chorea, either alone or accompanied with rheumatic polyarthritis or rheumatic carditis. Persons with onset after their fifteenth year showed a reversal of this picture. Only once in sixty-four times did rheumatic disease manifest itself in the form of chorea, while rheumatic carditis made its first appearance in nine cases. The relative risk of developing the disease was determined by dividing the number of onsets at each age by the "person-years at risk" for the corresponding age to obtain an annual incidence rate. This computation gave an average annual rate of 5.25 per thousand between the ages of 5 and 14 and 4.6 per thousand between 25 and 34 years. The incidence rate for the other ages indicated a considerably lower percentage of from 2.1 to 3 per thousand. The authors concede the limiting factors inherent in their study such as the inaccuracy of the data involving primary appearance of the disease and the possibility that the disease occurred in uncles and aunts not domiciled in an infectious environment. Since rheumatic disease is comparatively rare in children less than 3 years of age, the failure to obtain information at these age levels does not, in their opinion, invalidate the results.

Antibody Formation in Pneumonia After Sulfathiazole.—Kneeland and Mulliken determined the antibody production in the serum of twenty-one patients treated with sulfathiazole for lobar pneumonia. They used the precipitin reaction with type-specific polysaccharide for the demonstration of antibody formation. Before the introduction of sulfathiazole they studied thirty cases of pneumococcal pneumonia treated with sulfapyridine. In twenty-two of these, nearly 75 per cent, recovery from the disease occurred without the appearance of an excess of antibodies. Among the twenty-one patients treated with sulfathiazole, circulating antibody was detected in sixteen. The time of the appearance of the antibody was accurately determined in thirteen instances and its relationship to the beginning of normal temperature is known. In six of these the antibody appeared so close to the moment of "essential recovery" as to indicate that it might be playing an important part in that process. In six others the antibody was not detected until about a week after the temperature had been normal and in the remaining one not until three weeks had elapsed. It seems to the authors that the importance of these observations lies in the fact that a sharp difference is established between the response of patients treated with sulfathiazole and those treated with sulfapyridine. The types of patients, severity of disease and time of treatment were approximately the same in the two groups. Therefore the authors feel justified in concluding that a real difference exists between the responses of patients treated with the two drugs. The explanation which they believe probable is that sulfapyridine is a somewhat more powerful antibacterial agent in human lobar pneumonia than is sulfathiazole and that this difference expresses itself quantitatively in the proportion of patients who show a greater activity of their immune mechanisms when treated with the newer drug. Support to this hypothesis is lent by the fact that the sulfapyridine-treated patients averaged 1.7 days of fever after treatment was begun, while those on sulfathiazole averaged 3.2 days.

Pellagra in Average Population of Northern States.—Field and his associates point out that pellagra is not confined to alcoholic addicts and the Southern poor, among whom its severe manifestations are common, but lesser deficiencies, not accompanied by florid dermatitis, diarrhea or dementia, are common in the average Northern population. They are the cause of much impairment of health. One of the characteristics of chronic pellagrous dermatitis is hyperkeratosis. Common sites for hyperkeratoses are over skeletal pressure points: the knee, elbow, instep and front and back of the ankle. These lesions occur without known preceding acute lesions. The hyperkeratosis is occasionally nodular; it may have the roughness of sandpaper; there may be desquamation or the surface may be smooth and shiny. The hyperkeratotic often show pigmentation. Hyperkeratoses also occur over the soles of the feet. A fairly common hyperkeratosis is a more or less diffuse thickening of the skin over the fingers, especially the proximal phalangeal knuckles. Another common cutaneous manifestation is an ichthyosis-like change. These changes are easily overlooked or attributed to chapping. Ichthyosis is characteristically commoner and worse in the winter, and ichthyosis-like pellagrous scaling may be conditioned by

exposure to cold or heat. The usual site of ichthyosis-like changes is the anterolateral aspect of the calves, less frequently the forearms. When severe there may be a yellow-brown pigmentation. Lesser changes than a red, sore and atrophic tongue may suggest a pellagrous stomatitis. Occasionally the tongue is swollen and shows indentations from the teeth. It may appear normal except for redness with swelling of the fungiform papillae about the anterior edges and tip. Aphthous ulcers should always suggest the possibility of a pellagrous etiology. The nervous and mental symptoms, short of dementia or psychosis, are varied. Loss of energy, fatigability and weakness are usual complaints. Vertigo is common, as is uncertainty of balance, and sometimes staggering without vertigo. Paresthesias, such as numbness, burning or an itching or tingling sensation in the extremities and sometimes over the head, occur. A feeling of tenseness, irritability, mental depression, weeping without cause, insomnia, tremors and emotional instability are other common complaints. Constipation is perhaps the commonest and earliest gastrointestinal symptom. With a more severe deficiency, short spells of diarrhea may be interspersed with it. Abdominal discomfort after a small meal, sense of weight in the epigastrium or bloating are other signs. One of the most distinctive symptoms of a fairly severe deficiency is epigastric burning during or shortly after the ingestion of food, particularly acid food. An intrinsic etiology must be ruled out for the cause of the gastrointestinal symptoms. The authors found that doses of 60 mg. of synthetic nicotinic acid six times a day produced prompt results with no uncomfortable reactions until an adequate total dosage was determined. With such doses pronounced improvement in gastrointestinal and nervous symptoms should be obtained in less than a week. Chronic cutaneous lesions sometimes clear completely within two or three weeks. After the deficiency has been relieved, the diet should be improved so that further vitamin supplements will not be needed. Pellagra should be extended to those cases, lacking any cutaneous lesions, which have the same symptoms and are relieved by the same therapy. However, more important than the name is the recognition that such cases do occur, and not infrequently.

Visualization of Placenta.—Dippel and Brown used soft tissue roentgenography in examining 200 pregnant women. One fourth of these patients were so studied because of bleeding in the last trimester. The placenta was visualized in approximately 90 per cent of the cases; in the others deterring factors were present which rendered visualization difficult or impossible. Such factors were hydramnios, multiple pregnancy, unusual obesity of the mother and prematurity. Although with immature fetuses the chances of visualization are definitely reduced, the authors demonstrated the placenta clearly in a pregnancy advanced to only the twenty-fourth week. The position of the fetus does not deter good visualization. When the placenta is implanted over the lower uterine segment, its lower margin is usually not perceived. However, if one reasons that the normal placenta at or near term covers approximately one fourth of the surface area of the uterine wall, the probable type of placenta praevia may be diagnosed with reasonable accuracy. In a few of the patients the location of the placental site was checked at cesarean section or by vaginal examination, and in no case was the x-ray diagnosis erroneous. The future course of the pregnancy in all cases conformed to the x-ray diagnosis. Since the adoption of this technic, the number of vaginal examinations has been greatly reduced. After being roentgenographed, many patients are discharged to carry on the pregnancy and to be delivered normally at or near term. A single lateral roentgenogram is usually sufficient. Other applications of the technic offer possibilities. Before performing a cesarean section on a patient with an anteriorly located placenta, one might wish to take additional precautionary measures in the way of facilities for transfusion or to choose between a classic and a low cervical cesarean incision. Exact knowledge of the site of attachment before the insertion of bougies will guide one in selecting the anterior or posterior uterine wall for this and lessen the possibility of separation of the placenta. With the advent of soft tissue roentgenography the comparative thickness of the anterior uterine wall and the soundness of an old cesarean scar can

be determined. To date the authors have seen two cases in which the anterior uterine wall appeared irregularly thinned, and the patients were not permitted to go through normal labor. This thinning was subsequently confirmed at operation.

Clinical and Potential Allergy in Families.—Brem and Colmes determined the incidence of allergy among the families of forty allergic child patients whose relatives comprised 135 persons. Also seventeen persons of four normal families were studied. The study consisted of questioning about manifestations of past and present allergy, such as hay fever, vasomotor rhinitis, asthma, eczema, urticaria and angioneurotic edema. Cutaneous tests were made on each patient and relative alike. Forty (30 per cent) of the 135 relatives presented evidence of either present or past allergy. None of the seventeen members of the control families gave evidence in their histories of any of the common allergies. Data from cutaneous tests show that of the forty children with frank allergy 11 per cent of all the cutaneous tests were positive. Ten of the thirty-two fathers were allergic by history, and 5 per cent of the 360 cutaneous tests made on them were positive. On the other hand, the twenty-two nonallergic fathers showed an incidence of 2 per cent of positive tests. Likewise, the thirteen allergic mothers had three times as many positive tests as did the twenty-seven nonallergic mothers, 10 per cent and 3.4 per cent respectively, and the eight allergic brothers and nine sisters had a correspondingly higher ratio of cutaneous tests than did their forty-six nonallergic mates. In contrast to these results (more than 2 per cent) the total incidence of positive cutaneous reactions in the seventeen control members was less than 1 per cent. Potentially allergic persons are a challenge to the clinician. If allergy is to be successfully treated, it must be recognized before the disease has progressed to an advanced stage. The elimination of wheat, milk or feathers in a patient with corresponding positive cutaneous tests who has only minor symptoms, such as nasal stuffiness or a hacking cough, may ward off a much more serious illness, such as asthma or chronic sinusitis.

Relation of Chronic Mastitis to Mammary Carcinoma.

—Warren studied the relation of cancer to operations for benign noninfectious mammary lesions in 1,206 women. Of these 602 were operated on at the Toronto General Hospital and 604 at five Massachusetts hospitals. The follow-up for the majority of the patients was more than five years. Among all the chronic mastitis and chronic cystic mastitis cases (1,044) there occurred thirty-five cancers, representing a total exposure of 9,393 risk years. This gives the high rate of 3.35 per hundred as a crude rate, and 0.37 per hundred as a corrected or annual attack rate, taking the follow-up period into consideration. This contrasts with an average mortality rate of 0.029 per hundred, which is based on the Massachusetts female population in 1930, or a morbidity rate of 0.058 per hundred. When the age specific cancer attack rates per thousand risk years of the chronic mastitis group are calculated and contrasted with those per thousand risk years of the Massachusetts female population it is seen that the cancer rate for women with pre-existing breast lesions is 4.5 times as great as for all women. This predominance is especially marked between 30 and 49 years of age, when it is 11.7 times as great. Once a woman who has had chronic mastitis reaches the menopause, the chance of breast cancer developing is not much greater than that of any one, but until that time she is in far greater danger of having breast cancer than is the woman whose breasts have been apparently normal. This is despite the fact that the most abnormal or even all the abnormal tissue has previously been supposedly removed by surgical intervention. Actively proliferating lesions, intraductal papillomas and cysts with papillary epithelium were followed by cancer more often than the adenofibromas or large cysts with atrophic epithelium. In the light of the data presented it is impossible not to regard the woman who has chronic mastitis as being especially subject to the risk of cancer of the breast at some later date, should her mammary tissues be allowed to remain. There are two courses open: One, the more radical (and the less desirable), is to advise the patient to permit amputation of both breasts, as when the process has involved one breast it may well involve the other. The other alternative is, after removal of the definitely diseased tissue, to have her breasts carefully

checked at least every six months for evidence of abnormality. If encountered it should lead to a simple unilateral mastectomy if the lesion is benign and radical mastectomy if it is proved malignant. Even if not cancerous, the mastitic process will probably recur in breast tissue permitted to remain. Not only is the hazard of carcinoma real, but the persistence of the mastitic process is most striking. If intraductal papilloma or adenocystoma is encountered, simple mastectomy should be seriously considered. Other similar lesions may be present in the rest of the breast, and the transition to cancer is relatively easily made. Careful pathologic study is required to determine whether or not the epithelium is invading the surrounding tissue.

Pelvic Peritonitis in Female Children.—Schaufler encountered nine cases of primary pelvic peritonitis among 371 instances of genital infections in female children and infants. The youngest of the nine children was 3 and the oldest 14 years of age. Of the entire group 259 patients presented frank vaginal infections, of which 53 per cent were proved positive for gonorrhea and an additional 33 per cent suggested a gonorrheal origin. Three of the diagnoses were not clearly established, four were definite and two were highly suggestive. Six were frankly gonorrheal. The most serious case that came to operation was proved nongonorrheal. A severe pelvic inflammatory reaction developed in one child while under treatment by hypodermic theelin. Another had a typical pelvic flare-up in the presence of a gonorrheal vaginitis following a rectal injection of an antiseptic for associated gonorrheal proctitis. Two patients were suspected of having mild pneumococcal peritonitis but were not bacteriologically studied. Two were operated on and justify the conclusion that the very much higher incidence of appendicitis over pelvic infection in female children should be an important immediate consideration for operation. With the patient in good condition, less harm may be done by a mistaken operation for suspected appendicitis than by deferring operation under a mistaken diagnosis of primary gonorrheal pelvic inflammation.

Pathogenesis and Prophylaxis of Venous Thrombosis.—Frykholm states that his pathologico-anatomic investigations show that four areas of origin of incipient thrombosis are found: (1) the plantar veins, (2) the veins of the musculature of the calf, (3) the veins of the adductor musculature and (4) the visceral pelvic veins. From these areas the thrombosing process follows the blood stream. The four areas are influenced by some special local factors connected with the patient's position in bed and these factors gradually lead to injury of the intima of the vein. Three general conditions for the development of a thrombus must be considered: (1) a slowed down blood stream, (2) changed chemical composition of the circulating blood and (3) injury to the intima. The first two factors merely contribute to the pathogenesis and alone cannot give rise to a thrombus. The composition of the blood is changed in all morbid conditions and also after apparently aseptic operations. The blood acquires an increased tendency to coagulate. The changed chemical composition of the blood can by no means explain why a thrombus so often arises just within the four areas of origin. On the other hand, a sufficiently severe injury to the intima, even without the association of other factors, can always give rise to a thrombosing process. With a patient confined to bed the calves lie pressed flat against the mattress. The adductor region likewise is exposed to similar mechanical pressure. It is just these two groups of muscles which are least used by patients in bed. When a patient is confined to bed the greatest diminution of the flow of arterial blood is to the musculature of the calves and the adductor muscles. In an erect position the veins are distended to the maximum with blood. In a lying position the pressure on the veins diminishes and the veins collapse more or less completely. The collapse of the veins in the calf and adductor regions should be great, as they are also exposed to mechanical pressure. Therefore intima will lie pressed against intima, while a minimal stream of blood will percolate onward through a cracklike lumen which remains open in some part of the vessel. There is every reason to suppose that a somewhat prolonged contact of two intimal layers gradually produces an injury to the endothelium, thus bringing about a fundamental condition for the formation of

a small thrombus. From the surface of this thrombus substances are given off to the passing blood and these promote coagulation so that layer after layer of the blood mass becomes coagulated. The process moves with the circulating blood until finally a vein that was pressed together becomes completely distended with the thrombotic masses. The same explanation can be offered for the two other sources of thrombi, the plantar veins and the pelvic veins. Under normal conditions the plantar veins are kept distended by the highest blood column existing in the human body. In many persons confined to bed these veins will usually lie collapsed. In the pelvis meteorism, pregnancy and the like, possibly in conjunction with a failing circulation, may cause the veins to be insufficiently distended. If such pathogenesis is correct, then the prophylactic measures now employed must be altered. The method used by the author for a number of surgical and delivery cases which had been considered especially hazardous with regard to thrombosis was as follows: For from one to two hours daily the head of the patient's bed was elevated by placing the two head-legs on chairs. The movements made by the patient to maintain his position necessitates the use of the musculature of the calves and adductors. The venous pressure in the extremities rises and helps distend the veins. The position causes slight discomfort to the patient. None thus treated developed thrombi. As a further argument the author points out that as a rule the patient who remains free from thrombi is the one who is up and about a few days after operation. Patients should be placed in a position which resembles the upright as far as possible, and not in a position with the legs high. Before a patient is allowed to get up, the areas in which a thrombus usually develops must be palpated carefully. Palpation of the calf should be carried out with the two knees symmetrically semiflexed. The medial-posterior part of the thigh is thoroughly palpated bimanually. A slight increase in consistency or tenderness in deep-lying parts within this area is a valuable early symptom of thrombosis.

Sulfapyridine for Infectious Diarrhea.—Villani used sulfapyridine for the treatment of sixteen severe cases of infectious diarrhea in children from 2 months to 3 years of age. The condition was characterized by extreme high temperature and vomiting, the diarrhea being a watery green, tinged with blood and mucus. The infants were markedly dehydrated and, despite the prompt restoration of fluids and electrolytes, signs of bronchopneumonia, extreme cyanosis, pallor and marked respiratory embarrassment with a terminal pulmonary edema developed. As soon as the vomiting was controlled by elixir of phenobarbital, orange juice and physiologic solution of sodium chloride the patients were given boiled skim milk, sulfapyridine and small amounts of kaolin and camphorated tincture of opium. Physiologic solution of sodium chloride by hypodermoclysis, sips of orange juice and physiologic solution of sodium chloride by mouth control the vomiting, which as a rule is caused by the acidosis and dehydration. Patients were also given physiologic solution of sodium chloride enemas for abdominal distention and starch enemas for tenesmus. As soon as vomiting ceased infants were given a lactic acid milk formula and children, who respond rather promptly to this form of therapy, were given cereals, bread, custards and very ripe bananas in addition to their sulfapyridine medication. The author feels certain that in his sixteen cases sulfapyridine was a specific chemotherapeutic agent, as within twenty-four to forty-eight hours of the first dose of the drug the temperature dropped to normal and shortly thereafter the stools returned to normal. There was one death; the sulfapyridine was discontinued because the infant was unable to retain the drug. No serious complications were encountered. The minimal dose of the drug was administered.

Fate of Extracorporeal Circulating Hemoglobin.—

Fairley determined the fate of the extracorporeal circulating hemoglobin that is added to the circulation when blood and blood substitutes are transfused. Following the intravenous injection of from 14 to 25.4 Gm. of human hemoglobin a positive Schumm reaction was invariably demonstrated in the plasma within four to ten hours and persisted for twenty-four hours or longer. A transient increase in bilirubin was also present in the plasma of two of his three subjects receiving hemoglobin injections. Though the author could not demonstrate methemalbumin spectroscopically following the injection of these amounts of hemoglobin, it was demonstrated in the plasma of two patients who through an error were given incompatible blood containing approximately 45 and 90 Gm. of hemoglobin, respectively. In incompatible transfusion and the other intravascular hemolyses in man, methemalbumin and not methemoglobin is found in the plasma; a mixture of the two pigments has never been recorded in vivo, though they do occur together in vitro when a human plasma-hemoglobin mixture is incubated at 37 C. The conclusion reached from these investigations and from an extensive clinical study of hemoglobinurias and hemolytic anemias is that extracorporeal circulating hemoglobin is treated as a foreign substance in the body and that it disintegrates and is eliminated in as short a time as possible. The three mechanisms, depending on the concentration of extracorporeal hemoglobin attained in the circulation, called into action for this purpose are (1) absorption by the reticulo-endothelial system, (2) intravascular catabolism of hemoglobin and (3) renal excretion. It is suggested that hemoglobin disintegrating in the circulation is first split into globin and reduced hematin (ferrous); the latter pigment is immediately oxidized to hematin (ferric), which in man combines with serum albumin to form methemalbumin.

Rapid Method of Determining Reserves of Vitamin C.

—Pemberton presents experiments carried out to discover whether the concentration of vitamin C in a single specimen of urine passed four hours after a test dose of ascorbic acid would reveal the vitamin C reserves. Studies of the daily concentration of vitamin C in the urine of a normal adult were made eight days before and ten days after a test dose of 700 mg. of ascorbic acid. The subject had a diet which contained approximately 70 mg. of ascorbic acid daily. The average concentration of vitamin C before the test dose was 1.72 mg. per hundred cubic centimeters. Following the marked increase in concentration of vitamin C in the urine on the day of the test dose the concentration fell rapidly, and on the third day after the test dose the concentration in five out of six specimens was less than 2.3 mg. By the eighth day all the concentrations were less than 2 mg. and the total daily excretion was 19.9 mg. During the week following the test dose increases up to 7 mg. occurred on several occasions after the consumption of small amounts of fruit, showing a high degree of saturation in the tissues. The method employed in determining the concentration of vitamin C in the urine was the same as that described by Harris and Ray (1935). The study showed that the concentration in a given specimen of urine bore little relation to its volume but a definite relation to previously eaten fruit. In specimens passed between four and eight hours after the test dose there was a great increase in the concentration. The maximal concentration of 27.7 mg. was reached six hours after the test dose. In the twelve hours following the test dose 245.1 mg. of ascorbic acid was excreted. On the basis of these data the author believes that a subject whose diet contains moderate amounts of fresh fruit and vegetables will respond

to a test dose of ascorbic acid by yielding a high urinary concentration of vitamin C from four to eight hours after its ingestion. If this overflow occurred it might be presumed that the tissue requirements of vitamin C were being met, but if a massive dose of ascorbic acid produced no increase in concentration it would suggest that the tissues were depleted of vitamin C. To verify this hypothesis a test dose of ascorbic acid was given sixty-two orphan boys from 10 to 14 years of age who lived in an institution and whose diet was known. During the year immediately preceding the experiment half of the boys had been receiving additional dietary supplements, including a daily orange, as part of the Carnegie United Kingdom dietary and nutritional survey. The supplemented diet contained approximately 63 mg. of vitamin C per head daily, while that of the group on the basic orphanage diet contained approximately 35 mg. The boys on the lower intake did not respond to a test dose of ascorbic acid. The boys on the higher intake yielded a high concentration of vitamin C in the urine following a test dose of ascorbic acid. Therefore it may be presumed that there was no marked lack of vitamin C in the tissues of the latter and that a daily orange added to a diet containing approximately 35 mg. of vitamin C will in time produce a concentration in the tissues which is near saturation point. It is suggested that a child who responds to a test dose of ascorbic acid (50 mg. per stone [14 pounds, or 6.4 Kg.] of body weight) by yielding a marked concentration of vitamin C in the urine four hours later is receiving an adequate amount of vitamin C. If there is no response it may be inferred that the vitamin is being taken up to be stored and/or utilized and that there is a lack of vitamin C in the tissues. Whether this degree of lack is harmful it is impossible to say but, according to certain studies on infections, a child should not be considered adequately nourished unless there is an abundance of vitamin C in the tissues, determined by its overflow in the urine after a test dose of ascorbic acid.

Epidemic of Paratyphoid.—Anderson reports an epidemic of paratyphoid in Glasgow in March 1940 which lasted only four weeks and during which time 126 cases were admitted to the hospital, 70 per cent in the first week. The diagnosis was confirmed by bacteriologic study. In March 1936 Glasgow also had an epidemic of paratyphoid but its spread was over a period of twelve weeks with a peak in the sixth week. This suggests to the author that in the first epidemic a cause was operative over a protracted time, while in the latter the cause was a common one and it was operative over a short time. The high incidence of abdominal pain, vomiting and diarrhea (almost 50 per cent) favor a food poisoning type of infection—a "paratyphoid gastro-enteritis." The classic clinical characteristics of the enterica group (rash in eighty-one cases, enlargement of

spleen in eighty-eight and meteorism in seventy-one) were often encountered. In many cases the rash was profuse.

Simultaneous Whooping Cough and Diphtheria Immunization.—Through experiments on guinea pigs and rabbits, Schütze finds that whooping cough vaccine and alum precipitated diphtheria toxoid when administered simultaneously do not interfere with each other in their antigenic effects. In fact he says the effect of the toxoid is increased by the pertussis vaccine. He believes that it may be both convenient and effective to immunize children simultaneously against diphtheria and whooping cough.

Inner Bodies in Erythrocytes Caused by Sulfapyridine.—According to Moeschlin, cyanosis, which is frequently observed in patients treated with sulfapyridine or related substances, is ascribed by many investigators to the formation of methemoglobin. The fact that the spectroscopic search for methemoglobin is often negative in these cases is without significance, since concentrations of from 10 to 15 per cent are necessary in order to be detectable by this method. Prolonged and intensive treatment with sulfapyridine results in anemia. In the course of studies on a patient who developed a severe cyanosis during treatment with large doses of sulfapyridine the author observed, after vital staining with brilliant cresyl blue, the appearance of inner bodies in the erythrocytes. He made a systematic search for inner bodies in other patients treated with sulfapyridine and discovered in the same week four other cases in which inner bodies existed. The detection of inner bodies furnishes an indirect proof of the formation of methemoglobin in sulfapyridine therapy, because the appearance of large numbers of inner bodies has been observed only during methemoglobinemia. The observations prove also that the anemias developing in the course of treatment with sulfapyridine or related preparations are of hemolytic type. The author reports observations on the sternal marrow and on the reticulocytic reaction of two cases which demonstrate that the anemia is caused by a peripheral impairment of the erythrocytes and not by toxic impairment of the erythropoiesis in the bone marrow. The hemolyzing effect of sulfapyridine is demonstrated also by severe changes in the blood picture such as the appearance of spherical microcytes, severe anisocytosis, polychromasia and erythrocytes with basophil stippling. In one of the author's cases the formation of inner bodies (methemoglobin) led to such severe changes that a blood transfusion was necessary to counteract them. The author concludes that the blood picture should be controlled for inner bodies by examination with vital stains when large doses of sulfapyridine are given, when renal elimination is impaired and in cases of severe cyanosis. The appearance of inner bodies in a small percentage of erythrocytes is probably a frequent occurrence; it involves no particular danger but indicates that caution is necessary. When inner bodies appear in more than 200 per thousand erythrocytes the drug should be continued only in exceptional cases and under careful supervision. The appearance of inner bodies in 500 per thousand makes threatening complications and severe hemolysis likely.

Sulfapyridine in Children with Pneumonia.—According to Trachsler sulfapyridine was employed in 150 cases at the children's clinic in Zurich, 138 of which were cases of pneumonia. The fever disappeared within forty-eight hours after the treatment was begun in 88 per cent of the cases of lobar and focal pneumonia, in 50 per cent of the cases of bronchopneumonia, in 75 per cent of those children in whom the pneumonia developed after measles and in 50 per cent of those in whom the pneumonia complicated whooping cough. Sulfapyri-

dine exerted no noticeable effect on fully developed empyemas, but small effusions were promptly counteracted by it. On the basis of three cases the author suggests that the recurrence of pneumonia in the same child may be connected with the sulfapyridine treatment. Excluding the three patients who were moribund at the time of hospitalization, the mortality rate was 3.6 per cent. The daily dosage of 1 Gm. of sulfapyridine for each 10 Kg. of body weight proved effective; however, in nurslings it might have to be increased. Exanthems developed in four cases, but vomiting involved no difficulties. The author directs attention to the danger of giving inadequate doses at the onset of the medication. The diazo reaction of the urine is positive during the treatment with sulfapyridine.

*Behavior of Erythrocyte Sedimentation in Tonsillectomized Rheumatic Patients: Need of Preoperative Precautions. G. Costa Bertani.—p. 134.

Blood Sedimentation Before Tonsillectomy in Rheumatic Patients.—The frequency of uneventful routine tonsillectomies, according to Costa Bertani, induces a sense of security that may lead to postoperative complications if performed on rheumatic patients. He advises that the degree of active infection be gaged by sedimentation tests systematically given before surgical intervention, in order to prevent allergic shock and untoward reactions. Salicylic acid therapy capable of controlling pain in articular rheumatism and presenting an afebrile and apparently cured clinical picture does not constitute a sufficient indication. Observations based on a number of cases (eleven reported) showing a high erythrocyte sedimentation level (Katz formula) signified a high degree of toxic reabsorption. Patients who showed a low sedimentation level before operation presented the same picture after the operation and vice versa. In several cases in which the sedimentation count had been high, even a tooth extraction activated a return to higher levels, thus showing a clear connection between erythrocyte tests and infectious activity. Because of the correlation between high blood levels and infection, the author believes that tonsillectomy is contraindicated in the presence of articular rheumatism in full evolution unless all other therapeutic measures have failed. Serious articular or visceral complications may ensue if tonsillectomy is practiced on patients with a high sedimentation index though the clinical picture shows improvement.

*Nephrosis Due to Calcium Deposits in Pyloric and Duodenal Stenosis. E. Pérez Castro.—p. 1016.

Azoxulfamide in Two Cases of Tuberculous Meningitis. M. Sancho Lobo.—p. 1025.

Calcification Nephrosis in Pyloric and Duodenal Stenosis.—Pérez Castro investigated at necropsy fifty patients who died with manifestations of pyloric and duodenal stenosis after an antemortem history of prolonged vomiting involving serious loss of sodium chloride, together with fifty others who died from a variety of diseases. The uniform microscopic picture in five of the first group was a more or less pronounced accumulation of calcium deposits in the lumen of the uriniferous tubules, the epithelium of which was either flattened or had completely disappeared. In one case the calcification was covered with a new epithelial growth protruding from the canalicular lumen. In another case clinically and chemically diagnosed intra vitam as hypochloremia and treated with sodium chloride, no epithelial loss nor calcium deposits were observed, but only a serious albuminous degeneration of the tubular epithelium. Here the lesions secondary to hypochloremia had been checked by sodium chloride therapy. The author believes that renal lesions accompanying pyloric or duodenal stenosis are due to hypochloremia of which azotemia and uremia are only aggravated stages and that functional and morphologic renal changes coexisting with hypochloremia have heretofore been insufficiently investigated. In only three cases of the second group was some renal calcification found, but nephrotic lesions were absent.

THE MANAGEMENT OF INTESTINAL OBSTRUCTION

AN EVALUATION OF CONSERVATIVE THERAPY

CARL P. SCHLICKE, M.D.
Fellow in Surgery, the Mayo Foundation
J. ARNOLD BARGEN, M.D.
AND
CLAUDE F. DIXON, M.D.
ROCHESTER, MINN.

Nonoperative or conservative treatment of intestinal obstruction often leads to favorable and dramatic results. Because some authorities have stated that intestinal obstruction is invariably a surgical condition, we have felt it perhaps worth while to review the cases of intestinal obstruction encountered in the past year and to consider critically the value of conservative treatment.

The majority of reports that deal with nonsurgical decompression are concerned with acute obstruction of the small intestine. This study consists of the results obtained from treatment in cases of intestinal obstruction encountered at the Mayo Clinic from Aug. 1, 1938, to July 31, 1939, inclusive. All types of obstruction are included, acute, chronic, simple and strangulated, in both the large and the small bowel. Our chief purpose in this review is to obtain a broader and more inclusive evaluation of the role of conservative therapy.

Since the advent of aseptic surgery there have been two major advances in the treatment of intestinal obstruction: the demonstration of the value of parenterally administered fluids by the work of Hartwell and Hoguet,¹ MacCallum,² Haden and Orr,³ Dixon,⁴ Gamble and Ross,⁵ and the discovery of a method for decompressing the distended intestine by oral or nasal intubation as elaborated in the writings of Westermann,⁶ Ward,⁷ Wangensteen,⁸ Miller,⁹ Abbott,¹⁰ John-

ston¹¹ and others.¹² Aside from the inherent worth of these two therapeutic measures, their study and development have led to a better understanding of the problem of intestinal obstruction. The application of these principles together with the development of improvements in surgical technic has led in our experience to a great reduction of the mortality rate, which was formerly appallingly high.

The relative success of present day methods of dealing with intestinal obstruction as compared with the results of a decade or more ago is apparent in the mortality statistics of most large hospital services, such as those reported by vanBeuren and Smith,¹³ Scudder, Zwemer and Whipple,¹⁴ Kennedy and Hanson¹⁵ and others, and from the observations of other surgeons who have observed the transition.¹⁶

MATERIAL

The work at hand embraced a study of the patients, hospitalized during a period of one year beginning Aug. 1, 1938, who were found to have objective clinical evidence of intestinal obstruction at the time of admission or shortly thereafter. Cases of ileus attributable to operative procedures carried out during the patients' stay in the hospital were not included in this study. Patients who gave a history of obstructive episodes but did not present objective evidence of intestinal obstruction or patients whose only objective evidence of intestinal obstruction was found at operation were not included in this series. Obstructions situated proximal to the jejunum were omitted from this analysis.

METHOD OF STUDY

All cases were divided into two main groups, after the method of Wangensteen,¹⁷ simple obstructions and

peptic Problem in Bowel Obstructions.¹⁷ Wangensteen, Rea, Smith and Schwyzer.²⁰

cases in which there was thought to be a large functional element, cases in which, because of recovery without operation, the true cause was never determined, and three cases of the so-called enterorenal syndrome.¹⁸ Among the strangulation obstructions, inguinal hernia was the most common cause.

SIMPLE OBSTRUCTION

In table 2 the cases are classified according to the segment of bowel involved. We have divided these into three groups: cases in which the small bowel was the site of obstruction, cases in which the large bowel was obstructed and, finally, cases in which the whole intestine was distended because of adynamic ileus or in which the true nature and level of obstruction was not accurately determined.

Simple obstructions are customarily further classified as acute or chronic, complete or incomplete and early or late. However, as Morton¹⁹ has pointed out, the most important single factor in determining what treatment should be employed and what the outcome is likely to be is the general condition of the patient at the time of observation. This is the resultant of all other factors. In this study we have graded all simple obstructions as of high, medium or low grade. This grading was arbitrary, independent of the site of obstruction and determined on the basis of (1) the degree of distention, (2) the amount, duration and character of vomiting, (3) the duration and degree of obstipation, (4) the evidence obtained from a simple roentgenogram of the abdomen, (5) alterations in the blood chemistry and (6) the amount of colic and the character of peristalsis. Table 2 further indicates the incidence of the various grades of obstruction in the small bowel group, in the large bowel group and in the miscellaneous group.

MODE OF ONSET OF SYMPTOMS

The onset of symptoms tended to be acute or subacute in obstructions of the small bowel, whereas with obstructions of the large bowel there was a greater tendency to chronicity. In all groups the obstructions of high grade were more likely to be associated with an

acute or subacute onset than were the obstructions of low grade, in which the symptoms tended to be chronic or intermittent.

DURATION OF SYMPTOMS

The duration of symptoms ranged from a few hours to one or two years. The duration of certain symptoms was taken into consideration in determining the grade of obstruction. The duration of an acute attack could not always be correlated with the grade of obstruction: the duration of a chronic attack seldom could be so correlated.

DISTENTION

The degree of distention present, in general, corresponded with the grade which was assigned to the obstruction. The distention tended to be greater when associated with obstructions of the large bowel than with obstructions of the small bowel.

OBSTIPATION

The extent to which the bowels were "locked" to passages of fecal material varied considerably. In some of the obstructions of high grade a paradoxical diarrhea was present. In some of the chronic obstructions of low grade, days had passed without normal evacuation.

VOMITING

Vomiting was a prominent symptom in all groups but it occurred more commonly with obstructions of the small bowel (77.8 per cent) than with those of the large bowel (60.5 per cent). Fecal vomiting occurred with four of the high grade obstructions of the small bowel and with four of the high grade obstructions of the large bowel. Fecal vomiting occurred in one of the cases of low grade colonic obstruction as a result of the presence of a gastrojejuno-colic fistula.

BLOOD CHEMISTRY

The increased tendency for vomiting to occur with obstruction of the small bowel was reflected in the greater incidence of alterations in the blood chemistry in this group. Abnormal values for blood urea, chloride or carbon dioxide combining power were noted in 62.5 per cent of the obstructions of the small bowel and in

TABLE 2.—Simple Obstructions

50.9 per cent of the obstructions of the large bowel. That vomiting was not the only factor concerned was indicated in the preponderance of cases of acidosis over cases of alkalosis. Our observations were in accord with those of Falconer,²⁰ who pointed out that the most constant change and the one which gives the best index of the true condition of the patient is the elevation of the blood urea resulting from the increased metabolism of endogenous protein which occurs in the

presence of intestinal obstruction. This elevation varied directly with the grade of obstruction. The loss of chloride varied with the amount of vomiting. The level of the carbon dioxide combining power, as Falconer pointed out, was variable but in general in the presence of decreased chlorides it was elevated (alkalosis) and in the presence of normal values for chloride it was normal or decreased (acidosis). Under the influence of satisfactory treatment, whether conservative or surgical, the blood chemical values returned to normal, the urea usually more slowly than the other values.

PRECIPITATING FACTORS

The optimal time for operating on patients who have intestinal obstruction is in the interval between attacks in recurrent cases or, in any case, before the obstruction has become high grade in character. Accordingly, a search was made to determine if there were any factors responsible for the recurrence of attacks of obstruction or the exacerbation of attacks already in progress which could be avoided. It was found that six bouts of obstruction of the small bowel and nine bouts of obstruction of the large bowel had unquestionably been precipitated by the oral administration of barium sulfate for roentgenologic study. In four additional cases, barium sulfate had been given but the responsibility did not fall clearly on it. In two cases of obstruction of the large bowel and in one case in the miscellaneous group, bouts of obstruction followed the introduction of barium sulfate into the rectum. In one additional case the inability to recover adequately the barium thus administered might have played a role. Barium was not the only offender. Three attacks of small bowel obstruction and one of large bowel obstruction came on the heels of a strong purgative administered to prepare the patient for subsequent roentgenologic study.

Thus, in 133 cases of simple obstruction, the precipitation of an attack of obstruction in twenty-two cases (16.5 per cent) was caused by the administration of barium sulfate or too violent purgation and in an additional five cases (3.8 per cent) the barium seemed to be a factor in precipitating an obstruction. The hospital mortality of these twenty-seven cases was 33 per cent. Wangenstein²¹ has long emphasized the disasters which may follow the incomplete taking of a history, perfunctory physical examinations and too great dependence on laboratory data in cases of intestinal obstruction. Nowhere is this more clearly demonstrated than in these cases in which impaction of barium caused obstruction, cases seen with appalling frequency in spite of the repeated warnings of Dixon,²¹ Vernon David²² and others.

CONSERVATIVE THERAPY

All food and liquid orally is withheld in cases of obstruction of high grade. A "residue-free" diet (Bargen and Sister Victor²³) is permitted in the cases of low grade obstruction. Sedatives and antispasmodics are administered when it is felt that there is no danger of masking signs of impending perforation. Hot stupes are found to add materially to the comfort of patients. Rectal irrigations with warm physiologic solution of sodium chloride have proved especially valuable for obstruction of the large bowel. When the condition of the patient permits, these irrigations are administered

with the patient in the knee-chest position. By using this method, we have been able to relieve many obstructions of the large bowel after numerous unsuccessful attempts had been made by the use of ordinary enemas before the patient was admitted to the hospital. Cautious purgation with small doses of a saline laxative is employed in cases in which the obstruction is not complete. Balances of fluids and electrolytes are carefully maintained by the accurate charting of fluid intake and output and frequent blood chemistry determinations (urea, chlorides, carbon dioxide combining power). Intubation of the stomach or duodenum with continuous suction applied to the tube is employed in most obstructions of high grade and many of those of medium grade.

The Sawyer-Willson modification of the Miller-Abbott⁹ tube was used instead of the duodenal tube in a number of the cases of this series. Our experience with the tube in this group of cases is indicated in

TABLE 3.—Intestinal Intubation

Site of Obstruction	Number of Cases	Tube Used	Passage of Tube Difficult	Function of Tube		Final Results of Conservative Therapy	
				Satisfactory	Unsatisfactory	Satisfactory	Unsatisfactory
Small bowel	45	16	7 (15.6%)	12 (26.7%)	4 (8.9%)	12 (26.7%)	4 (8.9%)
Large bowel	76	20	6 (7.9%)	14 (18.4%)	6 (7.9%)	11 (14.6%)	9 (11.8%)
Miscellaneous	12	3	2 (16.7%)	2 (16.7%)	1 (8.3%)	3 (25.0%)	0
Total	133	39	15 (11.3%)	28 (21.1%)	11 (8.2%)	26 (19.6%)	13 (9.8%)

table 3. There was some difficulty in passing the tube in more than a third of the cases; either because of lack of cooperation on the part of the patient or because of extreme distention or other factors, several attempts were required to get the tube beyond the pylorus. In a few cases the tube never went beyond the stomach. In designating "function of the tube satisfactory" it is meant that the tube descended into the small intestine and drained intestinal content. In most cases of obstruction of the small bowel in which this occurred the final results of conservative therapy were satisfactory, but in a few cases, although the tube worked well, decompression was not accomplished. In one case this was found at operation to be due to complete obstruction of the lower portion of the ileum by a coiled tube. Unsatisfactory function of the tube signifies its failure to leave the stomach or plugging of the tube after it is in place. In a few cases the final results of conservative therapy were good in spite of a malfunctioning tube. In the group of cases of obstruction of the large bowel there is seen to be a marked discrepancy between the function of the tube and the final results. This can be explained by the fact that in only two of these cases did the tube pass into the colon. In the remainder the ileocecal valve prevented the tube from emptying the colon, although the tube might be the means of achieving satisfactory decompression of the small bowel proximal to the colon. The latter observation is in keeping with the observations of Johnston,²¹ who found the entry of the tube into the colon too uncertain and slow to be dependable. However, by preventing the ingress of further material from the small bowel into the distended large bowel, the tube no doubt was a valuable aid in the cases in which decompression of the large bowel was satisfactory.

In one instance the tube became coiled in the lower portion of the ileum causing complete obstruction and,

in another, there occurred collapse and general peritonitis soon after partial withdrawal of a tube the balloon of which could not be deflated.

High concentrations of oxygen, as recommended by Fine,²⁴ have been used in a few cases. In one case such treatment was attended by spectacular success but in a number of others it seemed to be without effect even though augmented by the more customary measures.

GENERAL RESULTS OF CONSERVATIVE THERAPY

The final results of conservative therapy at the time of its termination by operation, discharge or death are indicated in table 4. These were the clinical results and in most cases represented the opinion of the clinician in charge of the case and were not based on observations at operation or at necropsy. It will be seen that the results were satisfactory in the majority of

TABLE 4.—Immediate Results of Conservative Treatment in Cases of Simple Obstruction

Obstruction		Number of Cases	Benefited		Not Benefited	
			Complete Relief, Number and Percent- age	Partial Relief, Number and Percent- age	No Relief, Number and Percent- age	Condi- tion Worse, Number and Percent- age

	Medium	3	0	3 (100.0)
	Low	5	3 (60.0)	2 (40.0)
		12	6 (50.0)	6 (50.0)

cases of obstruction of the small bowel. The distribution of results was uniform in each of the three groups of cases of obstruction of the small bowel. In all cases in the miscellaneous group, benefit was derived. When we turn to the group of cases of obstruction of the large bowel, however, a striking contrast presents itself. The majority of the patients having obstructions of medium and of low grade were benefited; in fact, in a sizable proportion of these cases complete clinical relief was experienced. But, in the group of obstructions of high grade, more patients were unaffected by or actually harmed by the employment of conservative measures than were benefited. This, of course, is the group in which, because of a competent ileocecal valve and an obstructing lesion, one is dealing with what is essentially a closed loop.²⁵ It is the group against which warnings have been sent out by even the warmest advocates of conservative measures. Yet, at the same time, it is the group with which, because of the very poor condition

of the patient or the very good condition of the patient, one is most sorely tempted to temporize, although fully aware of the seriousness of the situation. It is hoped that this numerical demonstration of the fallacy of attempting conservative measures for high grades of colonic obstruction will serve to emphasize the importance of very careful continued observation in these cases and the employment of surgical intervention at the proper time. The proper time for operation may be at the moment when a patient is first seen, if the site of obstruction can be determined, or as soon thereafter as possible if no improvement is noted in the early hours of observation.

An interesting commentary on the results of conservative therapy is the fact that, in a group of forty-six cases in which complete relief of all signs and symptoms of obstruction occurred clinically and in which operation was then performed, twelve patients still exhibited marked distention of the bowel when the abdomen was opened. This should serve as a reminder to those who advocate radical operations in cases of recent obstruction that even in the face of complete clinical relief one is still not dealing with a normal bowel.

Complications Attending Conservative Decompression.—In the group of cases of obstruction of the small bowel, bronchopneumonia developed in one case and localized peritonitis developed in another, owing to a perforating type of lesion during the administration of conservative treatment. Serious complications were much more common in the group of cases of obstruction of the large bowel. Two patients experienced bronchopneumonia and five patients had localized peritonitis caused by subacute perforations of tumors or of the bowel proximal to the point of obstruction. General peritonitis occurred in six cases because of perforation of the colon proximal to an obstructing lesion and in one case because of the infection of ascitic fluid. In the miscellaneous group, pneumonia developed in one case. The fact that serious complications are limited almost exclusively to the group of cases of obstruction of the large bowel serves further to emphasize the hazards of temporization in dealing with grave obstruction of the colon. It is, of course, entirely possible that these complications may be the immediate results of the serious basic pathologic condition itself rather than the result of the attempt to relieve its symptoms.

OPERATIVE PROCEDURES

In the group of obstructions of the small bowel, emergency decompression by surgical methods was required in eight cases. In six cases ileostomy was performed; in one, ileostomy and colostomy were performed and in one an impacted gallstone was removed from the ileum; two of these patients died. In five cases no operation was performed because of complete relief of the obstruction by conservative methods. In one case operation was deferred because of the poor condition of the patient. In the remaining thirty-one cases, elective surgical procedures were performed. Obstructing bands or adhesions were released in ten cases, short-circuiting or decompressive procedures being added in four cases. No deaths followed these operations. Short-circuiting procedures were carried out in thirteen cases with two deaths. Resection of obstructing segments of bowel were carried out in five cases with one death. Three patients who had merely exploratory laparotomy died because of associated pathologic conditions. The group mortality for the

thirty-nine cases in which operation was performed was 20.5 per cent.

In the group of obstructions of the large bowel, proximal surgical decompression was carried out in fifty cases, in thirteen of which the obstructing lesion was exteriorized at the same time. Eleven of these patients died. Short-circuiting procedures were carried out in two cases with two deaths. Exteriorization of the obstructed region was carried out in four cases without a death. Resection of obstructed segments with anastomosis of the bowel was carried out in three cases without a death. Exploratory laparotomy alone was carried out for one patient, who survived. The group mortality for the sixty cases in which operation was performed was 21.7 per cent. In sixteen cases in the group of obstructions of the large bowel operation was not performed: in seven because of relief of symptoms by conservative measures, in four because of the poor condition of the patient, and in five because death occurred before operation was performed.

In the group of cases of miscellaneous obstruction, exploration was carried out in one case. In eleven cases no operation was performed because of relief of symptoms by conservative measures. There were no deaths in this group.

With the exception of two cases in the group of large bowel obstruction and one case in the group of small bowel obstruction, all operative deaths occurred among individuals whose obstruction was of a high grade.

Secondary operations were carried out mainly among the patients who had had obstructions of the large bowel. Thirty-six operations were performed with a mortality of 8.3 per cent. Two patients who had obstruction of the small bowel survived secondary operations.

GROSS MORTALITY

The figures for gross mortality are presented in table 5. There were 133 cases with twenty-nine deaths, a mortality rate of 21.8 per cent. The mortality rate was 0 in the miscellaneous group, 17.8 per cent in the small bowel group and 27.6 per cent in the large bowel group. The mortality rate was directly proportional to the grade of obstruction in the large and small bowel groups, being highest, as would be expected, in the group of cases in which obstruction of high grade was present.

CAUSE OF DEATH

Peritonitis was the most common cause of death, being responsible for the demise of four patients who had obstruction of the small bowel and thirteen who had obstruction of the large bowel. Six patients with obstruction of the large bowel died of pneumonia, one of gastrointestinal hemorrhage and one of pulmonary edema. Two patients with obstruction of the small bowel died of carcinomatosis; one of ileus and one of pulmonary edema. None of the patients in the miscellaneous group died.

Comments on Simple Obstructions.—It has been demonstrated that conservative measures greatly improve the general condition of most patients who have intestinal obstruction. In certain cases conservative treatment obviates the need for surgical measures. The one group consistently resistant to these salutary effects is the group of patients with high grade obstructions of the large bowel.

Intubation is an invaluable agent in the treatment of obstructions of the small bowel and is a helpful adjunct to the treatment of obstructions of the large bowel.

Irrigations find their greatest value in the treatment of obstructions of the distal half of the colon.

Fluid and electrolyte balances can be maintained by the intelligent administration of fluids parenterally.

The time required for successful conservative therapy is relatively unimportant.

The time element assumes major importance when conservative therapy is not progressing satisfactorily. As Wangenstein²⁶ has pointed out, the longer conservative therapy is continued the greater the hazard to the patient if it fails. No arbitrary time limit can be stated for the use of conservative therapy.

For obstructions of low grade the amount of time spent with conservative measures is optional.

For high grade obstructions of the small bowel, operation should not be deferred if there is no improvement from conservative measures after twelve to twenty-four hours.

In cases of high grade obstructions of the large bowel, which are essentially closed loop obstructions,

TABLE 5.—Simple Obstructions; Mortality

Obstruction		Number of Cases	All Hospital Deaths, Number and Percentage	Post-operative, Number and Percentage	After Second Operation, Number and Percentage	Without Operation, Number and Percentage
Site	Grade					
Small bowel	High	17	7 (41.2)	7 (41.2)	0	0
	Medium	12	1 (8.3)	1 (8.3)	0	0
	Low	16	0	0	0	0
		45	8 (17.8)	8 (17.8)	0	0
Large bowel	High	32	16 (50.0)	11 (34.4)	2 (6.3)	3 (9.4)
	Medium	23	3 (13.0)	1 (4.3)	0	2 (8.7)
	Low	21	2 (9.5)	1 (4.8)	1 (4.8)	0
		76	21 (27.6)	13 (17.1)	3 (3.9)	5 (6.6)

Total cases		133				
Total deaths			29 (21.8)			

conservative temporization is extremely hazardous. The condition of the patient may be improved by gastric lavage, administration of fluids parenterally and of sedatives, but operation cannot safely be deferred.

In all cases of obstruction, if the condition of the patient becomes worse rather than better under conservative therapy, immediate operation should be performed.

STRANGULATION OBSTRUCTIONS

Since attempts at conservative decompression have no place in the treatment of obstructions due to strangulation, with the possible exception of occasional cases of volvulus or intussusception prior to the development of gangrene, the treatment and results in this group of cases will be given only brief consideration.

There were thirty-three patients. All were subjected to operation. There were eight deaths, making a group mortality of 24.2 per cent.

26. Wangenstein, O. H.; Rea, C. E.; Smith, B. A., Jr., and Schwytzer, H. C.: Experiences with Employment of Suction in the Treatment of Acute Intestinal Obstruction; A Reiteration of the Indications, Contraindications and Limitations of the Method, *Surg., Gynec. & Obst.* 68: 851-868 (May) 1939.

Time of Operation.—Immediate operation was carried out in twenty-four cases with a mortality of 20.8 per cent. Operation was delayed six hours or more in nine cases. The operative mortality in this group was $33\frac{1}{3}$ per cent.

Condition of Strangulated Loop.—The strangulated loop was found viable at operation in twenty-three cases, in 8.7 per cent of which death occurred. The viability of the strangulated loop was questionable in one case. This patient died. The strangulated loop was gangrenous in nine cases; five (55.6 per cent) of these patients died.

Relation of Condition of Loop to Time of Operation.—Among the twenty-four patients who were subjected to immediate operation, the strangulated loop was found at operation to be viable in seventeen cases (70.8 per cent) and gangrenous in seven (29.2 per cent). Among the nine cases in which operation was delayed six hours or more, the strangulated loop was viable in six cases (66.7 per cent), gangrenous in two cases (22.2 per cent) and questionable in one case (11.1 per cent).

Treatment.—The type of operation performed depended on the condition of the strangulated loop. In the twenty-three cases in which the loop was viable, simple relief of the obstructing mechanism was performed in seventeen cases with one death. In three cases this procedure was augmented by enterostomy as an added precaution; one of these patients died. In three cases spontaneous relief of the obstruction was found to have occurred. The one patient in whom the viability of the bowel was questionable died following reduction of a volvulus that involved the entire jejunum and a third of the ileum.

Among the cases in which the strangulated loop was gangrenous, exteriorization of the affected loop was carried out in two cases without a death. In two cases the procedure was augmented by enterostomy; one of these patients died. Resection of the strangulated loop with primary anastomosis of the bowel was carried out in four cases, with enterostomy proximal to the anastomosis. Three of these patients died. In one case, volvulus was discovered at necropsy. In most of the cases in which a hernia was present, repair was effected in the process of closing the exploratory wound.

Cause of Death.—Peritonitis was the cause of death in five cases. Surgical shock contributed to the outcome in two of these cases; pneumonia also was present in a third case. Shock alone caused two deaths. One patient died of uncomplicated pneumonia.

Comments on Obstructions Due to Strangulation.—The time element is very important in these cases. The longer operation is delayed the greater the likelihood that gangrene will develop or, if gangrene is already present, the greater the likelihood that general peritonitis will develop.

The presence or absence of gangrene determines the difficulty and extent of operation and the gravity of prognosis.

Operation should be performed in all obstructions due to strangulation as soon as the diagnosis is established in cases of external hernia or as soon as there is anything to suggest the diagnosis in cases in which there are internal lesions.

Loss of blood may be an important factor in obstructions due to strangulation, and transfusions are of great value in these cases.

SUMMARY

The results of treatment in 166 cases of intestinal obstruction were studied. This number included 133 cases of simple obstruction and thirty-three cases of strangulation obstruction. The incidence of avoidable precipitating factors to which bouts of acute obstruction could be attributed is relatively high. All patients who had simple obstruction were subjected to a period of conservative therapy for varying lengths of time before operation. In a number of cases this therapy obviated the need for surgical intervention.

The results of conservative therapy were found to be satisfactory in most cases of simple obstruction of the small bowel and of low and medium grade obstruction of the large bowel. The results of conservative therapy were distinctly unsatisfactory in high grade obstructions of the large bowel, and in certain of these cases the results were disastrous.

The recognition of high grade obstructions of the colon when they occur and the avoidance of dangerous temporization in such cases is important. The gross mortality rate for all cases of simple obstruction was 21.8 per cent. In the various groups the mortality rate was found to be directly proportional to the grade of obstruction. The treatment of the obstructions due to strangulation was strictly surgical. The mortality rate in this group was 24.2 per cent.

HEMORRHAGIC DIATHESIS OF
THE NEWBORNFURTHER OBSERVATIONS CONCERNING PRE-
VENTION AND TREATMENT

W. W. WADDELL JR., M.D.

AND

GEORGE McL. LAWSON, M.D.

UNIVERSITY, VA.

It has been fifteen years since Dam¹ announced the discovery of vitamin K and described its antihemorrhagic properties. In the past two years we have seen proof of the valuable properties of this newcomer to the family of vitamins in two important clinical fields, namely the hemorrhagic state associated with obstructive jaundice and the hemorrhagic diathesis of the newborn. The rapid development in the chemical synthesis of vitamin K stands out as a landmark of accomplishment in the field of biologic chemistry.

In March 1939 we² recorded the cases of two newborn infants both with marked prothrombin deficiency. In one infant there was in addition unnatural bleeding. To each of these infants natural vitamin K concentrate was administered orally, and within the short interval of two hours the prothrombin deficiency appeared to have been corrected and bleeding in the one instance promptly was controlled. On the basis of these few facts we suggested that vitamin K might serve a specific purpose in the prevention and treatment of hemorrhagic

The vitamin K preparations used in this study were provided through the Abbott Laboratories and E. R. Squibb & Sons.

disease of the newborn. In April 1939 one of us³ described before the Society for Pediatric Research and later published in June 1939 certain additional data based on the study of ten control infants and ten K-treated infants to the effect that prothrombin deficiency and its associated bleeding were the direct result of avitaminosis K. We further stated at this time our belief that this same bleeding setup was perhaps present at birth and might in fact be responsible for certain cases of birth injury, particularly in those cases in which symptoms and signs of intracranial hemorrhage were late in developing. We suggested that, if prothrombin deficiency in the infant could be prevented by oral or parenteral administration of vitamin K to the mother, birth accidents might be materially lessened.

Over a period of one year we have made 2,232 prothrombin time and clotting time determinations on 191 control and 181 K-treated infants. These data have all been published or accepted for publication.⁴ We have further recorded additional cases of unnatural bleeding associated with hypoprothrombinemia, including that of hemorrhagic disease. Observations similar to ours have subsequently been reported by others working along identical lines.⁵ These additional data have verified in general the observations and therapeutic suggestions contained in our preliminary reports. The necessity of conserving space does not permit us to review again the fast accumulating data on this subject.

Our purpose in this article is to record additional facts of a laboratory, clinical and statistical nature concerning the hemorrhagic diathesis of the newborn and birth injury.

All prothrombin times were done by the Bray modification of Quick's method, which permits the use of capillary blood. Thromboplastin samples were prepared with acetone and all readings between fifteen and twenty-five seconds were considered as normal.

The top curve in chart 1 shows the average prothrombin time of 189 controls on admission at the end of twenty-four, forty-eight, seventy-two, ninety-six and 144 hours. It will be seen that the period of most marked deficiency occurred at the age of forty-eight and seventy-two hours. Of the 189 control cases, 111 showed some degree of prothrombin deficiency. In certain instances prothrombin deficiency was actually present in cord blood or shortly after birth.

The lower curve in chart 1 shows a similar prothrombin average for twenty-three premature infants. In this short series prothrombin deficiency was less apparent

than that of the full term infants. A forty-eight hour peak is apparent also in this group of infants.

Chart 2 shows the correlation between prothrombin time and clotting time of the blood in nineteen consecutive cases observed in March 1940. All clotting times were done by the capillary tube method. This correlation has been constant throughout the entire study. As the prothrombin time rises and falls so does the clotting time.

We have on one previous occasion called attention to an apparent seasonal variation of the incidence of prothrombin deficiency in the newborn. That such a seasonal variation does occur is evident from the facts described in chart 3. The highest prothrombin time encountered in each of 191 consecutive control cases was ascertained and the average prothrombin time for each calendar month is shown in the top curve. The same results in a series of 189 consecutive treated cases are shown in the lower curve. The break in the curves for the months of April and May mark a necessary interruption in the progress of this study. The following facts are evident: 1. Prothrombin deficiency

Chart 1.—Average prothrombin time of control cases.

occurred with surprising frequency in the control series. 2. No such deficiency is evident in the treated series. 3. A period of marked prothrombin deficiency in the control cases occurred during the winter months, reach-

UNTREATED

CASE 1.—Bleeding from circumcision for three hours. Prothrombin seventy-seven seconds. Clotting time six and one-half minutes.

CASE 2.—Bleeding from clipped tongue frenulum and heel of five hours' duration. Prothrombin seventy-five seconds. Clotting time ten minutes. Controlled in two hours with vitamin K.

CASE 3.—Vomited blood on two occasions. Bleeding from cord and heel puncture for five hours. Prothrombin three and one-half minutes. Controlled with vitamin K in three and one-half hours.

CASE 4.—Bleeding from fontanel and heel punctures of fourteen hours' duration. Paralysis of right side of face and nystagmus developed. Died of intracranial hemorrhage on second day. Cord blood prothrombin one minute forty seconds. On day of death, prothrombin time eleven minutes. Clotting time above fifteen minutes.

CASE 5.—Cephalematoma at birth. Prothrombin time forty seconds at forty-eight hours.

CASE 6.—Bled from heel puncture for two hours. Prothrombin time six minutes. Clotting time nine minutes.

CASE 7.—Premature infant. Died on fourteenth day. An unsuspected intracranial hemorrhage found post mortem. Prothrombin time twenty-six seconds. Clotting time five and one-half minutes.

CASE 8.—Bleeding from scratches on face and puncture wound in heel for four hours. Prothrombin time eight minutes. Clotting time eight minutes. Controlled by vitamin K in two and one-half hours.

CASE 9.—Bleeding from heel puncture for three hours. Prothrombin seventy-two seconds. Clotting time eleven minutes. Controlled with vitamin K.

CASE 10.—Bleeding from heel puncture for nine hours. Prothrombin fifty-five seconds. Clotting time twelve minutes. Controlled with vitamin K.

CASE 11.—Large cephalematoma. Prothrombin at twenty-four hours thirty-five seconds. Clotting time nine minutes.

CASE 12.—Profuse bleeding from clipped tongue frenulum for seven and one-half hours. Epinephrine packs, local epinephrine injections and silver nitrate cauterization tried without success. Prothrombin time sixty-five seconds. Clotting time ten minutes. Controlled with vitamin K in three and one-half hours.

CASE 13.—Bled from circumcision for five hours. Prothrombin thirty-two seconds. Clotting time six and one-half minutes. Controlled with vitamin K in one hour.

CASE 14.—Spontaneous bleeding from mucous membrane of mouth for two hours. Prothrombin forty-eight seconds. Clotting time nine minutes. Controlled with vitamin K in one and one-half hours.

CASE 15.—Six day old child bleeding from cord following trauma. Had bled for twelve hours. Prothrombin time fifty-nine seconds. Clotting time eight minutes. Vitamin K given and in two hours prothrombin was thirty-one seconds and clotting time six minutes. In eight hours clotting time had dropped to three minutes.

CASE 16.—Profuse bleeding from heel puncture wound for seven hours. Prothrombin thirty-five seconds. Clotting time six minutes. Controlled by vitamin K in one hour.

CASE 17.—Bleeding from heel puncture for twelve hours. Prothrombin time seven minutes. Clotting time eleven minutes. Controlled with vitamin K in two hours.

CASE 18.—Profuse bleeding from heel puncture wound for two hours. Prothrombin two and one-half minutes. Clotting time seven minutes. Controlled with vitamin K in two hours.

CASE 19.—Seen on fourth day. Marked respiratory difficulty. Moribund. Signs of fluid in right chest. Died in about thirty minutes after admission. Postmortem examination revealed massive hemorrhage in right pleural cavity. Prothrombin time done immediately after death was three minutes forty seconds.

CASE 20.—Hemorrhagic disease of the newborn. Intracranial hemorrhage with death on eighth day. Clotting time fourteen minutes. No prothrombin time done.

CASE 21.—Bleeding from heel puncture. Clotting time nine minutes. No prothrombin time done.

CASE 22.—Bleeding from cord for twelve hours and also bleeding from heel puncture for several hours. Clotting time eleven minutes. No prothrombin time done. Controlled with vitamin K in two hours.

CASE 23.—Intracranial injury. Patient was slightly lethargic on fifth or sixth day but diagnosis did not become obvious until the seventh day, at which time convulsions appeared. Craniotomy performed showed definite contusion of the right hemisphere. This was a private patient and was not included in the prothrombin studies. Clotting time four minutes and bleeding time one minute on seventh day.

TREATED

CASE 24.—Baby admitted in poor condition after a hard labor. Mother received vitamin K for two weeks before labor. Child developed definite spasticity, had slight convulsions and refused food. The prothrombin time and clotting time on this child were normal throughout hospital stay. On discharge, this child was clinically well. No demonstrable intracranial signs were present.

CASE 25.—Precipitous labor. Moderate sized cephalematoma noted at twenty-four hours. Mother received no vitamin K before delivery. Baby received natural vitamin K concentrate on admission and at end of twenty-four hours. Clotting time on third day was four minutes.

CASE 26.—Moderate amount of bloody vaginal discharge noted on fourth day. This continued for a period of four days. No other abnormal tendencies. Clotting time on admission four minutes and, after forty-eight hours, three and one-half minutes. Mother received synthetic vitamin K intravenously eight hours before delivery. Baby received synthetic vitamin K by mouth on admission and at end of twenty-four and forty-eight hours. No prothrombin deficiency was noted at any time.

CASE 27.—Mother received intravenous vitamin K one hour and seventeen minutes before delivery. Small cephalematoma noted twelve hours after admission. Clotting time on admission three and one-half minutes.

COMMENT

It seems unlikely that hypoprothrombinemia and associated hemorrhage will occur in any newborn infant adequately treated with vitamin K through its mother and supplemented in the first few days of life. Prothrombin deficiency, so commonly present in the first few days of life, is the immediate cause of bleeding in hemorrhagic disease, and prothrombin deficiency is in turn the result of avitaminosis K. The etiology, prevention and treatment of hemorrhagic disease of the newborn would appear to be well established.

The role of hemorrhagic disease as a factor in birth injury has in the past been a matter of some controversy. Most writers on this subject have placed scant emphasis on any inherent tendency of the newborn infant to bleed at the time of delivery and would attribute the varying degrees of intracranial hemorrhage commonly occurring at this time to trauma alone. The laboratory, clinical and statistical data here described would indicate that avitaminosis K and associated prothrombin deficiency may well be a very real factor in many of these cerebral accidents, particularly in those infants in which the signs of intracranial hemorrhage are late in appearing, indicating that the hemorrhage is of a slow oozing character. Although trauma is the precipitating factor, the extent of existing damage may well depend on the degree of prothrombin deficiency. At the present time every infant born in the University of Virginia Hospital is treated with vitamin K through the mother and

this treatment is supplemented by oral administration of vitamin K in the first few days of life. Our experience to date convinces us that hypoprothrombinemia and associated neonatal hemorrhage will not occur in infants so treated and that so-called traumatic birth injury has been and will continue to be materially lessened.

ABSTRACT OF DISCUSSION

DR. CLIFFORD SWEET, Oakland, Calif.: A method of asking parents for autopsies which has proved successful is given each year to the new house officers. In our first approach, my associates and I assure the parents of our sympathy and tell them that we want to offer them one more real service—a complete examination of the body of their child. That we want to spare them the doubts that often assail people for years after the death of a member of the family. That often, even years afterward, people have returned to me and have said through their tears, "Doctor, I wish I had let you do that postmortem examination and then I would really know whether or not his death could have been prevented." That some disease may be found in the body which should be discovered for the sake of other members of the family, for example, miliary tuberculosis. Since we have placed first emphasis on the value to the family of the postmortem at the Children's Hospital in Oakland, where at least half of our patients are cared for as private patients, the autopsy percentage has remained for years about 80 and has at times risen to 90. Postmortem examinations are especially important on the bodies of newborn infants. By no other means can the real cause of death be determined and the family be assured that no condition is present which might affect the welfare of future infants born to them. In addition, the family can be spared the distress which so often ensues from their mistaken idea that they lost their child because of faulty obstetrics, as for example the infant with all the signs of a birth injury who at postmortem was found to have a cerebellar abscess of intra-uterine origin and a recently observed absence of muscle tissue in the diaphragm incompatible with more than a few weeks of life. I congratulate the authors on this work and on their modesty in drawing conclusions. I shall go home and make use of their excellent teaching.

DR. CHESTER BROWN, Arlington, N. J.: I should like to ask the authors to give the exact details of the administration of vitamin K to newborn infants. Do they add bile salts and, if so, in what amount and by what method?

DR. W. W. WADDELL JR., Charlottesville, Va.: With regard to Dr. Brown's question as to the details of the administration of vitamin K, the following procedure has been found quite adequate: Five-tenths cc. of natural vitamin K concentrate or its equivalent in the form of 2-methyl-1, 4-naphthoquinone administered immediately after birth and at the end of twenty-four and forty-eight hours will adequately prevent prothrombin deficiency in the newborn. One cc. of natural vitamin K concentrate or its equivalent in the form of 2-methyl-1, 4-naphthoquinone administered daily to the mother in the last ten days of pregnancy will prevent prothrombin deficiency in the offspring. We have never seen a single infant treated in either of these fashions which developed prothrombin deficiency. At the present time we are using synthetic products exclusively and believe that when they come on the market they will be the preparations of choice. They can be procured at a much lower price.

Common Sense.—Three fifths of the practice of medicine depends on common sense, a knowledge of people and of human reactions. More than half of the remainder is technological and mechanical, the work of those medically trained artisans we call surgeons. What remains may be termed preventive; and this in bulk very properly and inevitably comes to be taken over by the state, though people, being what they are, find ways of evading a disagreeable statute as in the case of compulsory vaccination—intended for others but not themselves. Not everybody obeys the traffic light, and every regulation breeds its jay-walkers and its racketeers.—Cushing, Harvey: *The Medical Career and Other Papers*, Boston, Little Brown & Co., 1940.

CLIMATE AND MILITARY PREPAREDNESS

CHARLES I. SINGER, M.D.

LONG BEACH, N. Y.

Any plan for military preparedness based on a defense of this hemisphere would be incomplete without proper consideration for the role of climatic factors in American warfare. Adherence to the Monroe Doctrine may necessitate the sudden dispatch of troop units with considerable striking power sufficient to prevent invasion or to break enemy footholds in any part of the Americas. Extending from one arctic region to the other, the Americas present all types of climate and all varieties of climatic change. Diseases caused by abrupt climatic change or by prolonged exposure are manifold and constitute important problems of preventive medicine in warfare. Troop movements, therefore, must always carefully take into account the degree of climatic change involved lest the efficiency of the fighting force be considerably, even dangerously, impaired. It is my purpose in this paper to outline the principal factors of this important problem and to present a basic and practicable plan for its solution.

By "climate" I mean the sum total of meteorologic phenomena that characterize the average state of the atmosphere at any given locality. "Weather" is only a phase—a single act—of this succession of phenomena. Climate is a long range view on weather.

Out of the complexity of coeffective factors in climate one may separate temperature, humidity, winds, barometric pressure and sunshine duration as the most important in relation to human life. These are the factors which determine the heat absorbing capacity of the atmosphere, which means the rate of heat absorption from any given body surface with a given temperature expressed in calory/square inch/minutes. This heat absorbing capacity of the atmosphere is proportionate to the difference between the temperatures of the body surface and of the atmosphere; it is influenced by humidity and by barometric pressure and it increases with the square root of wind velocity.

HUMAN COMFORT

The individual feels comfortable when his heat production is in equilibrium with the heat absorbing capacity of the environment. Every person has a characteristic comfort zone. When this heat equilibrium is upset so that either chilling or perspiration results, the limits of the comfort zone have been exceeded. The limits of the individual comfort zone depend on, and fluctuate with, seasons, time spent indoors and outdoors, clothing, activity, age, sex and constitution. Outside the comfort zone the human organism is confronted with various problems. If the heat absorbing capacity of the environment diminishes, heat loss is accomplished by vasodilatation in the skin and perspiration; heat production is diminished by lower muscular tone and lowered basal metabolic rate. In a cold environment (increased heat absorbing capacity) heat preservation is the problem. This is performed by vasoconstriction of the cutaneous blood vessels, increased muscular tone and a higher basal metabolic rate. In a change of season the heat absorbing capacity of the environment changes more or less gradually. Thus, going from fall to winter, the heat absorbing capacity increases. This gradual change extends the lower limits of the comfort zone, so that

indoors one is comfortable at a temperature five or six degrees Fahrenheit lower than the same room in summer. A corresponding elevation of the upper limit of the comfort zone occurs during the gradual change from spring to summer. No hardship is imposed on the organism in adjusting to such a slow change. In a sudden change, however, such as rapid movement of troops from temperate to subarctic regions, the necessity for quick adaptation is forced on the body. This requires maintained vasoconstriction and a sharp rise in the basal metabolic rate, which, if prolonged, may produce deleterious effects. Prolonged and repeated nasal vasoconstrictions lower the resistance of the mucous membrane, a faulty reflex which may be an important factor in the causation of infections of the upper respiratory tract. The importance of respira-

changes in the external environment, while the use of clothing and heating constitutes an indirect defense. The average American, following the instinct to seek comfortable temperature levels, has a limited comfort zone as a result of clothing and indoor heating—a reliance on indirect defense. A systematic extension of the comfort zone by direct methods of hardening American troops, especially those who may face the rigors of arctic warfare, is imperative for full fighting efficiency.

It is not sufficient to adapt soldiers to sudden climatic changes alone. They must be able to endure prolonged climatic exposures associated with physical strain. This is the real measure of the stamina of the individual. There is a limit of endurance, which may be called "peak performance," the level of which can be raised by training. The example of lack of stamina with good climatic adaptation is provided by the Russian soldiers in the recent war in Finland. The divisions annihilated north of Lake Ladoga were healthy, hardy young Russians, well clothed for action in such climates and trained in the Russian steam baths to endure sudden changes in temperature. However, they were not able to withstand the rigors of prolonged exposure to the Nordic winter of Finland. Fundamentally, these were instances

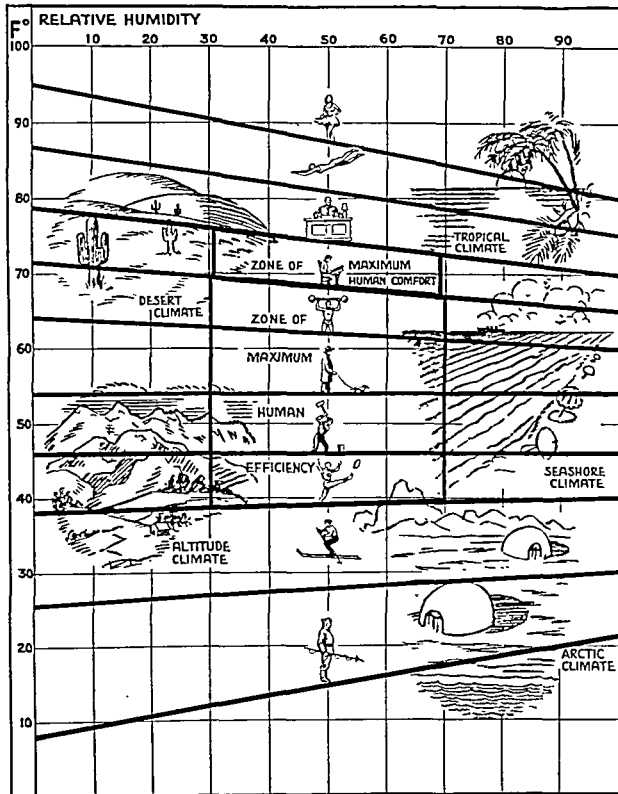

Fig. 1.—Illustrated climatogram, showing all possible combinations of humidity and temperature and zones of maximum human comfort and efficiency. Lines of effective temperature connecting points of equal human comfort comprising different combinations of temperature and humidity (heavy lines). Adapted to environment by exposure, clothing and activity, man feels comfortable along extremely differing lines of effective temperature.

tory diseases in relation to fighting efficiency of troop personnel is self evident. This was much less a factor in the old style of trench warfare—the war of position—than in the modern tactical maneuvers involving rapid movements of troops over great distances. In trench warfare soldiers with acute respiratory diseases were kept at a short distance in the rear, were considered as reserves and were returned to the front line in from seven to ten days. In a war of movement they are completely lost as effectives.

HARDENING

By means of planned, gradual, repeated exposures, the limits of the individual comfort zone may be expanded—a process known as hardening. Through the hardening process the system acquires a direct defense mechanism against sudden and marked

Comparative Morbidity Among Fresh and Seasoned Troops

	Company A, City to Tyrol, 248 Men, Number of Cases	Company B, Russia to Tyrol, 242 Men, Number of Cases
Common cold (without fever).....	32	10
Tonsillitis	12	4
Influenza	28	7
Pneumonia (lobar)	8	2
Appendicitis	3	0
Rheumatic fever (acute).....	3	1
Fibrositis	12	4
Total morbidity	98—39.5%	28—11.5%

The low morbidity rate among the troops hardened in Russia speaks for itself on the value of conditioning.

of units pitted against one another in a test of endurance requiring peak performance, and the Russians failed.

In the recent Norwegian campaign the French sent troop units of the Foreign Legion into action. These men were trained in a desert climate with extreme variations of temperature, both high and low, combined with low humidity. The fluctuations of temperature in desert climates are due to a loss of heat through radiation at night. This is gradual, and one blanket at night is sufficient to compensate in protecting a soldier from this change. In Norway, with its predominantly low temperatures, high wind velocity and high humidity, a climatic adaptation too great to be made suddenly was imposed on the legionnaires. This further illustrates poor judgment in a warfare requiring climatic changes. The dispatch of French Alpine Chasseurs was indicated in this case. In the rout of the English at Steinkjer, clothing inadequate for northern Norway was a contributing factor.

Abrupt climatic change may bring to the fore latent diseases such as tuberculosis, arthritis, heart disease and respiratory infections. Not only may latent diseases come forth but general resistance to acute infections tends to be lowered. For example, during the first world war I was detailed as a medical officer with two companies of infantry to clear up the high mountain road on the side of the Becco di Filla Donna mountain in the Austrian Tyrol, which was buried under an avalanche of snow. The time was March 1916, the

altitude was 14,000 feet. We started from the Adige valley with an average temperature of 60 F. to reach a wind swept site the average temperature of which ranged from 30 to 35 F.

Company A had been stationed in the valley for about six weeks and was composed of raw recruits from cities. Company B had arrived ten days previously after an all winter campaign through Russian Poland—a company of seasoned, hardened fighters. It took us three days to accomplish our task, working in the snow, wind and rain twelve hours a day, and sleeping in the primitive deserted stone huts of mountain shepherds. In a five day period, beginning with the first day of our assignment, the list of comparative morbidity was as shown in the accompanying table.

From this one may conclude that the ideal of physical fitness in the soldier of war should include:

1. Ready adaptability to sudden and extreme climatic change.
2. Ability to endure prolonged exposure to extreme change.
3. Maintenance of peak military efficiency in either or both of the aforementioned instances.

SUGGESTIONS FOR THE UNITED STATES ARMY

1. The training of recruits should start in the fall of the year. The gradual change to winter affords a parallel to gradual hardening by progressive exposure. These series of exposures to a climate growing increasingly rigorous is the best method for obtaining climatic adaptability whenever possible. Recruits starting next April under the present conscription plan will require at least ten months to obtain the adaptability acquired by the October group in five months.

2. The entire system of training troops has been based on summer maneuvers in the North and winter maneuvers in the South. In my opinion this procedure should be completely reversed to provide troops trained for both extremes—subarctic rigor and tropical mugginess.

3. Climatic adaptability can be furthered in training by frequently repeated hydrotherapy. The procedures to be recommended are (a) surf or river bathing wherever possible, (b) cool and gradually cooled showers as a part of the daily routine and (c) Scotch douche apparatus with alternating hot and cold streams of water. Those hydrotherapeutic processes are especially useful in the hardening of soldiers with poor climatic adaptability and in increasing self confidence and military morale—a very important military consideration.

4. A low average temperature of winter barracks, not exceeding 65 F., is recommended in training. Observations over several years show that the number of colds in apartment houses increase with a rise of indoor temperature above 70 F.

5. Parallel with this suggestion (lowering the temperature of the barracks), studies should be made on the vestimental climate of the soldier by frigorimetric methods, with different clothing materials and large series of cutaneous temperature readings under these materials. The clothing of the new United States Army will thus be based on scientific selection with due consideration for the climatic requirements of the region in which it is to be used.

6. Individual climatic endurance charts are recommended as aids in determining the adaptability of the soldier of whom special duties may be required. These charts should include:

- (a) Line of chilling at different humidities.
- (b) Line of perspiration at different humidities.

(c) Basal metabolic rate in both regions.

(d) Behavior of skin and rectal temperatures in planned exposure:

(1) Convergence of cutaneous and rectal temperatures after a short exposure shows faulty heat regulation: domestication.

(2) Divergence of cutaneous and rectal temperatures (rectal temperature increased, cutaneous temperature drops) after exposure indicates acclimatization.

(c) Ice cube test for thermic reacting ability of the skin:

(1) Delayed local hyperemia appearing later than ten seconds after two seconds contact with an ice cube indicates poor thermic reacting ability of the skin.

(f) Erben's test for determining autonomous nerve balance:

A positive Erben's test is a slowing down of the pulse rate by more than ten beats per minute after forced forward bending. It shows vasomotor instability, noted usually in vagotonic individuals. Persons with a positive Erben's reaction are poor risks in climatic exposure unless hardened.

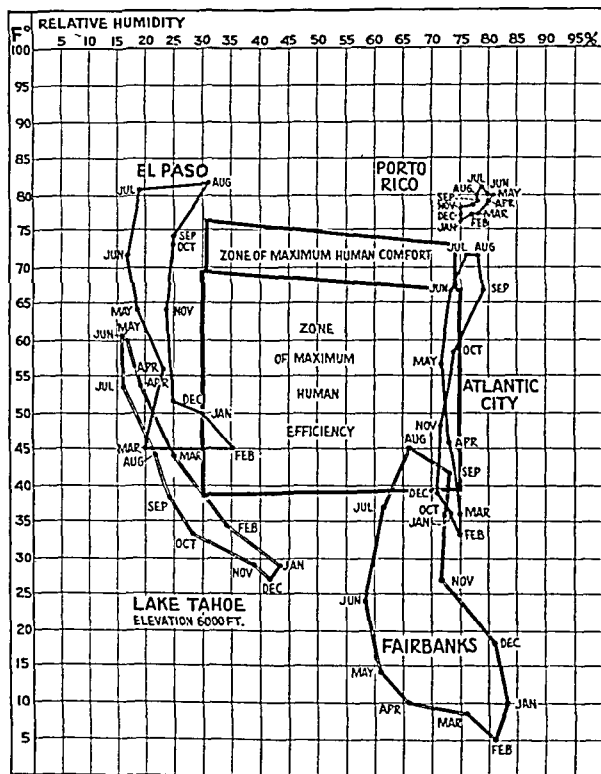

Fig. 2.—Comparative climatogram. The climatogram, which covers all possible combinations of temperature in degrees Fahrenheit and relative humidity (per cent saturation), has projected on it the zone of maximum human comfort and the zone of maximum human efficiency. Silhouetted against these zones are the monthly temperature and humidity averages of different localities representative of different climatic types. Characteristics of climate types represented are:

Puerto Rico, tropical: negligible fluctuation of a high temperature level, high humidity, lack of winds; enervating debilitating climate.

Fairbanks, Alaska, arctic: moderate fluctuation of an extremely low temperature level, high humidity; exhausting climate.

Lake Tahoe, Nevada, high altitude: extreme diurnal and seasonal range of temperature, low humidity, low barometric pressure, low oxygen content, high ultraviolet quality in solar radiation; stimulating climate.

El Paso, Texas, desert: extensive diurnal and moderate seasonal range of temperature, extremely low humidity, abundant sunshine; moderately stimulating climate.

Atlantic City, seashore: moderate diurnal, marked seasonal changes in temperature, high relative humidity, vigorous sea breezes; stimulating climate.

(g) Changes in blood chemistry: Completed acclimatization is noted by definite characteristic changes in the blood chemistry involving a change in the levels of phosphorus, calcium, sugar, carbon dioxide combining power and cholesterol.

(h) The modified Muck test: This will discover endocrine imbalance by showing inability of maintaining the blanching of the nasal mucous membrane following topical application of epinephrine. After complete acclimatization (increasing the sympathetic tonus) the vasoconstriction in the nasal mucosa

is maintained beyond fifteen minutes and blunt irritation of the blanched area causes a characteristic elevated white streak reaction.

7. Artificially controlled climatic testing laboratories for some of the foregoing tests may be readily reproduced with modern air conditioning apparatus. It will therefore be possible to select men for special tasks from among those who can adapt most quickly to changes in environment as observed in artificially controlled test rooms. Thus a yardstick on which to base the training of others will also be provided. Seven million dollars has been appropriated for an army aviation test station at Fairbanks, Alaska, to be ready in November, to study the behavior of airplane motors in arctic climates. This is a very necessary establishment, yet little provision has been made for testing the climatic adaptability of the most important military machine—the human body. Such tests should be conducted both at rest and during varying degrees of activity in different clothing.

8. As previously stated, the Western Hemisphere includes every type of climate and every type of geological milieu. If the possibility exists that troops may have to be sent to any of these sites, a larger body of troops especially trained for the climate must be organized. This applies at present more to troops needed in subarctic zones than to those for tropical use. Other acute needs envisage desert and mountain (high altitude) troops. For a clearer understanding of climatic problems, a climatogram is presented.

9. The climatogram is a graph prepared to compare climates of different places in the United States as expressed in monthly temperature and humidity averages. Superimposed are the zones of maximum human efficiency, both mental and physical, and the zone of maximum human comfort. Also shown are lines of effective temperature depicting equivalents of human comfort at varying temperatures and humidity. This means that a person is as comfortable at 84 F. and 40 per cent humidity as at 88 F. and 80 per cent humidity with an 8 mile breeze blowing, other conditions being equal. The limits of the zone of comfort of any person are given as perspiration at one end and chilling at the other. The process of hardening extends the comfort zone in the direction of chilling as an expression of increased adaptability.

In warfare the climatogram is useful in that it shows graphically the extent of a climatic change involved in a required military maneuver.

It also shows the relations of climate of the new environment with zones of maximum human efficiency and comfort. From the military point of view relativity in human reaction to climatic change is most important. The climate of the site of previous training in relation to the climate of the proposed site will greatly influence the adaptability and the efficiency of the troops. For example, in winter in the temperate zone greater efficiency may be expected of troops trained in subarctic regions as compared with troops trained in subtropical environments.

10. The present climatic health resorts and spas can be used if needed for the rehabilitation of convalescents. Most of these resorts are located in salubrious climates. A climate void of extremes, sedative in character, is especially recommended for convalescents. The employments of all types of natural resources and facilities of the resorts can be best accomplished by medical men well acquainted with them.

11. Each climate has its optimal diet. It should be used as far as possible to enhance adaptation. A high fat, high protein, high calory diet is advisable in cold climates. A high carbohydrate, low fat and protein, low calory diet is advisable in tropical climates. Owing to a lack of fresh vegetables and fruits in cold climates there is a lack of minerals and vitamins in Nordic diets. Tropical soils are poor in minerals and rich in humic acid and fruits and vegetables are plentiful but are poor in minerals. Loss of mineral salts through perspiration is an additional factor. Hence the administration of concentrated mineral and vitamin pills are advisable in extreme climates, both arctic and tropical.

12. Creation of a special climatic advisory board comprising meteorologists, physicians, physiologists, physiochemists, chemists and biochemists is advised. Their function should be:

- (a) Further study of climatic factors in warfare.
- (b) Establishment of standards of training by evaluation of results of training in climatic relationship.
- (c) To act in a consultant capacity in troop movements.
- (d) To set the standards for distribution of convalescents to proper climatic milieus.

STERILITY IN THE MALE

DIAGNOSIS AND TREATMENT

HENRY A. R. KREUTZMANN, M.D.

SAN FRANCISCO

Sterility in the male is an exceedingly complex subject entailing exhaustive urologic, endocrinologic and laboratory studies. For the purpose of simplification, all cases can be divided into two groups, urologic and endocrinologic. Occasionally malnutrition or vitamin deficiency may cause sterility, but it occurs so infrequently that for practical purposes it need not be stressed. The paper is limited to the study of sterility as it affects the human being, as the result of current animal experimentations are not analogous to those found in man.

The urologic cases are classed as either congenital or acquired, depending on the etiology. The most frequent congenital causes of sterility are hypospadias, cryptorchism and abnormal attachment of the epididymis to the testicle. The majority of acquired cases are the result of a former gonorrheal infection resulting in bilateral epididymitis, stenosis of the ejaculatory ducts, seminal vesiculitis, vasitis and urethral stricture.

The endocrinologic cases are due to atrophy of the testicles, pituitary dysfunction and hypothyroidism.

The study of sterility must include a complete history and examination of the genito-urinary tract. In the history, the following questions should be stressed: Age at puberty, number of years married, any children by previous marriage, contraceptives used, type or method and how long; mumps, age and complications; syphilis; gonorrhea, duration, complications; operations on genito-urinary tract; injuries to genital tract; urologic symptoms; sex life.

In the physical examination the penis should be examined for hypospadias or scars; the urethra for stenosis of the meatus, discharge or stricture; the testes for cryptorchism, atrophy, nodules on the epididymides or thickening of the vas deferens; rectal palpation to

determine the size and consistency of the prostate and the condition of the seminal vesicles. The examination should also include a basal metabolism test.

UROLOGIC ASPECTS

Aspermia is due either to atrophy of the testes or to an inflammatory occlusion situated somewhere between the globus major and the ejaculatory ducts. When the testicles are normal, one can be certain that the lack of sperm is due to obstruction. It is then important to establish the exact point where it occurs so that the proper treatment may be given to overcome the obstruction.

Stenosis of the ejaculatory ducts can be determined by the failure of the seminal vesicles to empty after massage and the absence of seminal fluid in the expressed secretion. The patient also gives a history of pain or burning sensation in the perineum or rectum at the moment of ejaculation and in some cases for several hours afterward. The treatment is to dilate the ducts with bougies passed through a urethroscope.

To determine the patency of the vas, I inject solutions into the lumen through small incisions made in the scrotum. For injection material 5 per cent mild protein silver is used on one side and 2 per cent mercurochrome on the other. Before the injections are made, a urethral catheter is inserted into the bladder. When both vasa are patent, the solutions appear immediately from the outer end of the catheter. If one solution does not appear, one knows definitely which side is blocked. I have attempted to relieve the obstruction in the vas by passing fine probes or forcibly injecting solutions into the lumen, but with only occasional success. One is handicapped by the fact that this is an operative procedure and repeated attempts cannot be made as in the case of a urethral stricture.

When both vasa and ejaculatory ducts are patent, the absence of sperm is due to an obstruction in the epididymides. In these cases the most successful treatment is Hagner's method of anastomosing the vas deferens to the efferent ducts of the globus major, thereby sidetracking the epididymis.

Chronic seminal vesiculitis can produce a depressant action on sperm, reducing their motility to such a degree as to prevent conception. Long continued massage and heat will remedy this condition.

In hypospadias, even though the slit is small, the improper deposition of the secretion may prevent pregnancy. The simplest method of overcoming this condition is for the patient to have intercourse wearing a condom with a small opening at the end.

A severe urethral stricture may prevent conception by preventing sufficient sperm being deposited in the vagina. Chronic prostatitis is not a cause of sterility, as I have examined men with families in whom the prostatic secretion was loaded with pus cells.

Cryptorchism can be corrected either with glandular therapy or with the Keetley-Torek operation. Treatment should not be delayed after puberty as it is now known that, the longer correction is withheld, the greater is the destruction of the spermatogenic function of the testicle.

ENDOCRINOLOGIC FACTORS

If the urologic examination is negative, one can correctly assume that some endocrine dysfunction is present. This supposition can be proved by an examination of the sperm. In a study of the ejaculate the three most important factors are (1) the number of

sperm per cubic centimeter, (2) the percentage of abnormal forms and (3) the degree of motility.

The work of Hotchkiss¹ has shown that the previous concept of man being sterile if the sperm count is below 60,000,000 per cubic centimeter is incorrect. In his work on 200 men whose wives were pregnant, Hotchkiss found counts as low as 2,250,000 per cubic centimeter and in 25 per cent of the men the count was below 60,000,000.

Moench² states that the number of abnormal sperm should not exceed from 19 to 20 per cent. He assumes that fertility is impaired when abnormalities reach from 20 to 22 per cent and that clinical sterility is usually present if more than 25 per cent abnormal forms are found.

In a series of forty-eight men whom I was able to follow over a period of years, 35 per cent had less than 20 per cent abnormal sperm and pregnancy occurred in every case without any treatment, bearing out Moench's conclusions. All of the patients showing abnormalities of the ejaculate can be classified into four groups.

1. Normal sperm count and normal percentage of abnormal forms with a lowered basal metabolic rate.
2. Oligospermia and a normal percentage of healthy sperm.
3. Normal number of sperm with an increase of abnormal forms.
4. Oligospermia with an increase of abnormal forms.

Fifteen per cent of the patients were in group 1, having a basal metabolic rate varying from minus 10 to 18. They were all given thyroid by mouth, following which the desired results were obtained.

Patient S. was most instructive. He was entirely normal except for a metabolic rate of minus 16 when first seen in 1934. Chorionic gonadotropin was given

Abnormal Forms After Twelve Injections of 5 Mg. of Testosterone Propionate

	Before Treatment	After Treatment
Case 1.....	24%	19%
Case 2.....	14%	17%
Case 3.....	18%	17%
Case 4.....	31%	31%
Case 5.....	27%	33%
Case 6.....	28%	50%

for four months with no result. Thyroid was then administered continuously, and in November 1935 his wife became pregnant. For the next three years thyroid was discontinued. He returned in June 1938, as they were anxious to have another child and his wife had not become pregnant again. Thyroid was again administered and three months later she became pregnant.

It is in groups 2, 3 and 4 that occasional brilliant results, but mostly failures, are reported after the administration of endocrine products (Heckel,³ Hotchkiss,⁴ Browne,⁵ Rubinstein and Kurland⁶).

3. Heckel, N. J.: The Gonadotropic and the Gonadotropic-like Factor in the Treatment of Male Sterility, *Endocrinology* **22**: 111-114 (Jan.) 1938.

4. Hotchkiss, R. S.: Methods in Sperm Analyses and Evaluation of Therapeutic Procedures, *J. A. M. A.* **107**: 1849-1851 (Dec. 5) 1936.

5. Browne, O'Donel: Hormonal Treatment of Male Sterility, *Irish J. M. Sc.* **6**: 618-621 (Aug.) 1939.

6. Rubinstein, H. S., and Kurland, A. A.: Effect of Testosterone Propionate on Spermatogenesis in Human, *South. M. J.* **32**: 499-503 (May) 1939.

Little is known about the endocrine changes that cause sperm to become abnormal in men who are apparently healthy and show no glandular disturbances. Therefore the administration of endocrine products at the present time is entirely experimental and will continue to be so until the glandular dyscrasias which cause changes in the sperm are known for certain.

It is impossible to explain why a group of men each receiving the same androgen or gonadogen for the same condition, as for example oligospermia, should react differently. In some instances there will be an increase in the number of sperm, whereas in others there will be no change. Marked increase in the number of abnormal forms may also occur in one man while a decrease will result in another. The only consistently good results of glandular therapy at this time occur in those cases in which the thyroid function is deficient.

In the zeal to treat sterility, one must guard against the inclination to use large doses of androgens, estrogens and gonadotropic agents or to administer them continuously for long periods. I have seen aspermia develop in a patient with 34 per cent abnormal forms after receiving 0.5 cc. of chorionic gonadotropin three times weekly for two months. Examination of the same patient one year later showed only a few sperm present with 25 per cent abnormal forms.

Another patient with 26 per cent abnormal forms received 2 cc. of pregnant mare's serum three times a week for one month. Following the injections the abnormal forms increased to 74 per cent. After a rest period of one month they dropped to 31 per cent.

At the present time testosterone propionate is the androgen most frequently used by physicians in the treatment of both impotence and sterility. Heckel⁷ and McCullagh and McGurl⁸ have shown that this drug when used in doses of from 25 to 50 mg. caused a decided decrease in the number of spermatozoa. However, according to the observations of Rubinstein and Kurland⁶ the administration of small doses of testosterone, 5 mg. three times a week, caused an increase in the number of sperm.

Encouraged by their results, I studied the effect of small doses of testosterone propionate on the abnormal sperm of six patients. In three men the percentage was within normal limits and in the other three there was a pathologic increase in the abnormal forms. Testosterone propionate was injected three times weekly in 5 mg. doses for one month. As can be seen from the table, there was no consistent change after the administration of the drug. In two patients with an increased number of abnormal sperm before treatment the drug caused a further increase in pathologic cells, while in the third patient there was no change.

In view of the harm that may occur, the indiscriminate injection of endocrine products should be stopped. One should be especially cautious in the use of large doses over long periods of time as the pathologic changes in the sperm may be increased by such treatment.

It is advisable to make repeated sperm analyses during the administration of these potent drugs in order to guard against transient or possible permanent damage to the spermatogenic structures of the individual.

SUMMARY AND CONCLUSIONS

All cases of male sterility can be divided into two groups, urologic and endocrinologic. The urologic cases are either congenital or acquired.

Studies of patients should include a complete urologic history, examination of the genital tract and of the ejaculate, and a basal metabolism test.

The endocrine treatment is at present in the experimental stage. Results cannot be attained in all cases until the glandular dysfunctions which cause sterility are known.

At present, it is only in cases of hypothyroidism that consistently good results are obtained.

The administration of large doses of testosterone propionate causes marked decrease in the number of spermatozoa per cubic centimeter. The injection of 5 mg. of testosterone propionate three times a week for one month caused no appreciable change in the percentage of abnormal forms in patients with both normal and abnormal sperm counts.

Caution should be exercised in the administration of large doses of endocrine products over long periods of time.

Repeated sperm analyses should be made during treatment to guard against transient or possible permanent damage to the spermatogenic structures of the individual.

THE NATURE OF HUMAN INFERTILITY

SAMUEL R. MEAKER, M.D.

AND

SAMUEL N. VOSE, M.D.

Professor of Gynecology and Associate Professor of Genito-Urinary Surgery, Respectively, Boston University School of Medicine
BOSTON

The average couple seeking relief from sterility in the year 1920 had about a 20 per cent chance of accomplishing their desire if they were fortunately able to consult one of the half dozen physicians in this country who were at that time devoting particular attention to the subject. In the hands of other doctors, including eminent gynecologists and urologists, the likelihood of success was only half as great. Today there are many groups of expert workers whose percentage of cures ranges from 40 to 50. It would seem that the profession has some right to congratulate itself on this striking improvement in the management of a problem which is vitally important in the lives of more than 2,000,000 American homes and consequently, in the aggregate, of no small importance to the social and economic welfare of the nation.

Huhner's method of postcoital examination and the Rubin test of tubal patency initiated a long series of technical advances, among which may be mentioned more precise and critical evaluation of the semen, better approaches to the assay of endocrine functions, and the use of both endometrial and testicular biopsies. Indeed, investigation and the interpretation of observations have now progressed to a point at which little of a factual nature needs to remain obscure in the physical status

Read before the Section on Urology at the Ninety-First Annual Session of the American Medical Association, New York, June 14, 1940.
The conclusions reported in this paper are based in large part on an organized group study of sterility, initiated in 1927 at the Evans Memorial for Clinical Research and Preventive Medicine, a unit of the Massachusetts Memorial Hospitals.

of a childless couple, excepting only the question of whether or not mature ovulation occurs. There still exists, however, a considerable misconception of those basic principles which underlie a reproductive failure on the part of two apparently healthy individuals, principles which must be understood if investigation and treatment are to be carried out intelligently. At the risk of repeating certain ideas previously voiced by us and other workers, we propose in this paper to consider some of the fundamental details of the nature of infertility.

During the past thirteen years it has been our privilege to carry out the investigation of childless marriages as a group endeavor. Experience has confirmed certain theories on the causation of sterility which were responsible for the establishment of the group and has afforded information of great utility in the selection of proper therapy. Results have amply justified the routine use of diagnostic procedures which in some cases were perhaps unnecessarily elaborate and at times inconvenient. Although the members of the section to which this communication is addressed are particularly concerned with the urologic aspects of the subject, it should again be emphasized here that only by a thorough inquiry into the condition, constitutional as well as genital, of both husband and wife can improvement in the percentage of successful results be expected.

The distribution of responsibility between husbands and wives can be appreciated only when one takes into account the important principle of multiple causation. In a minority of cases, perhaps 30 per cent, there exists some condition which alone and by itself is sufficient to make conception impossible. Such absolute factors of sterility would be exemplified by atrophy of the testes and by occlusion of the genital passages of either sex. The majority of cases present multiple abnormalities, generally of lesser grade. One or two of these might be overcome by nature, but several of them acting together lower the combined fertility of the couple to a point inconsistent with the production of offspring. Important factors of this type are certain constitutional faults which because of their subclinical character, often give little hint of their presence. With regard to this group of conditions it is not easy to reach precise conclusions as to cause and effect, since many instances of such abnormalities are found in ordinarily fertile individuals. But the persistent appearance of a given pathologic condition among the faults discovered in the examination of sterile couples at least raises the suspicion that it is significant as a possible causative factor; and this supposition gains support when correction of the condition in question is repeatedly followed by an objectively demonstrable improvement in fertility.

Of interest in this connection are statistics obtained during recent years from couples subjected to that complete group study which we believe necessary for the best interests of patients. In a consecutive series of 200 cases, all without exception showed at least two conditions capable of exerting a depressing effect on fertility. One case presented nine such factors, and three cases eight factors each. The average incidence was 4.8 factors per case. Many of these abnormalities were, of course, entirely unsuspected prior to the investigation, since they had no evident effect on the general health. It should be noted that the rule of multiple causation holds true even in absolute sterility; sixty-

nine such cases occurred in this series, and every one of them presented secondary factors of infertility in addition to a principal cause.

The concept of sterility as a matter of divided responsibility, rather than as a fault ascribable entirely to one or the other partner, has been abundantly emphasized in the literature. Nevertheless its truth is still too seldom recognized in practice. Although the days have happily disappeared when the wife was regularly subjected to dilation and curettage as the first step in the management of a sterility problem, the husband's semen being examined only as a last resort and then only casually, there still exists an unfortunate tendency to treat the first discovered abnormality in each case on the unwarranted assumption that no other faults are present. Thus time is fruitlessly wasted, whereas a more adequate survey, taking both partners into account, might have led to success. The fact is that, in 90 per cent of childless couples seeking the help of the physician, some evidence of infertility can be demonstrated in both members of the pair.

Numerous estimates have been offered on the comparative importance of sterility in the male and in the female. These vary remarkably, depending on the approach to the problem and the experience of the individual author. From ancient times, most of the blame for childless unions has been assigned to the wife. One writer, on the other hand, has indicted the husband in 100 per cent of cases, on the grounds that all sterility is due to gonorrhea and that all gonorrhea is the fault of the male. The quantitative data at present available on the question of divided responsibility allow only approximate conclusions. Our own experience indicates that, of all demonstrable abnormalities known to militate against fertility, some 30 per cent occur on the male side. The statement just made expresses the numerical division of factors between the sexes, and nothing more. It should not be interpreted as asserting that the male is responsible, either wholly or chiefly, for 30 per cent of barren marriages. While it is true that around 90 per cent of the husbands in our cases have proved to be more or less infertile and that some 40 per cent of them show notable deficiencies, one still cannot say to what degree any given man is to blame for the sterility of his particular mating unless one takes into account also the reproductive capacity of his partner. A recent tabulation made by us on this basis gives, in summary, the following results: Out of 100 cases the male was entirely at fault in eight and the female in fourteen. In the remaining seventy-eight cases the responsibility was divided, being chiefly male in twelve cases, equal in fifty-one and chiefly female in fifteen.

These figures seem to offer a rare opportunity and a definite challenge to urologists, who as a group have devoted comparatively little interest to problems of human reproduction. When one considers, however, that more than 12 per cent of all marriages are involuntarily childless and that 30 per cent of the pathologic conditions underlying this state of affairs occur on the male side, it seems evident that the matter of infertility in men is worthy of the serious attention of the urologic profession. Increasing recognition of the importance of male responsibility has already proved to be one of the outstanding advances of recent years in the field of sterility research and practice.

It has also come to be recognized that constitutional causes of infertility, significant enough in both sexes,

have in the male an aggregate importance far greater than that of local abnormalities of the genital organs. This fact in no wise lessens the need for the expert services of the urologist, since in the last analysis it is he who must correlate all data on the male partner, make a diagnosis, direct treatment and determine progress. As a matter of routine he identifies, and treats as indicated, disorders falling within his major field. Those most serious with relation to sterility, notably atrophy of the testis and occlusion of the epididymis or vas, have showed a comparatively small incidence among our cases. Other derangements, such as varicocele, chronic prostatovesiculitis and stricture, are of more frequent occurrence but of much less importance as causative factors of impaired fertility.

In a large majority of cases of male deficiency the principal trouble is the depressing effect on the spermatogenic function exerted by one or another type of constitutional disturbance. No other interpretation suffices to explain abnormal morphology of the spermatozoa, a condition now well understood to be a direct evidence of infertility. Among constitutional faults of the sort in question, those most frequently encountered are endocrine disorders, chronic intoxications from infectious or other sources, and poor hygiene in the matters of diet and exercise.

Normal spermatogenic function depends on two processes: hormonal stimulation provided by one or more fractions of the product of the anterior pituitary lobe, and response to that stimulus on the part of the tubular epithelium of the testis. It appears that constitutional disorders can decrease fertility by interfering with either of these processes: in other words, by inducing a state of anterior pituitary insufficiency or by diminishing the reactivity of the germinal epithelium. In any case the degree of malfunction produced will vary not only according to the severity of the depressing influence but also according to the inherent strength of the sex cells. Thus it happens that a given constitutional fault may render one man sterile while it has no appreciable effect on the reproductive capacity of another. Thus also are explained wide differences in the benefits obtained by treatment of apparently similar cases. Moreover, the permanence of the harm done is determined by the age at which the causative factor becomes operative. Pituitary failure at puberty is likely to result in testicular hypoplasia, and although the endocrine balance may later stabilize itself there will remain a stigma which can never be removed once the growth impulse is dead. The same endocrine disturbance appearing in adult years leads simply to functional underactivity of an organ normally developed, a disorder often amenable to treatment.

Although anterior pituitary insufficiency is the commonest among endocrine factors of subnormal spermatogenesis, the routine administration of gonadotropic substances should be condemned. Accurate diagnosis is prerequisite to proper treatment, since there are many conditions, endocrine and other, that may produce the same subnormality. The hypothyroid cases, which are fairly numerous, form an interesting group. Often these patients present none of the classic signs or symptoms of myxedema; a diagnosis can be made only on the basis of the metabolic rate and other laboratory measurements. The semen in general is good, except for a slight increase in the incidence of abnormal morphology. In other words, the fundamental trouble in such a case

is so little evident that it would rarely be discovered without complete diagnostic study. But successes following thyroid treatment are now numerous enough to remove all doubt about the cause and effect relationship of that trouble to infertility. As regards the internal secretion of the testis, at present too little is known to warrant dogmatic pronouncements about its influence on the reproductive processes. Androgenic substances appear to stimulate the accessory glands of the male genital apparatus and also to improve sexual desire and performance. Their effect on spermatogenesis is uncertain.

The chronic intoxications most important with reference to infertility are those which originate within the body from foci of infection, notably in the mouth and in the nasal sinuses. It is a question whether the toxins circulating in the blood stream directly poison the germinal epithelium or whether they act primarily by depressing endocrine function. In favor of the latter hypothesis is the fact that not only in sterility but also in many other disorders the efficacy of organotherapy is relatively diminished as long as chronic focal infections are present. One of the commonest conditions found in sterility cases is chronic prostatovesiculitis. In the past it was thought that this condition depresses fertility by creating an environment hostile to the spermatozoa while they are passing through the genital ducts. To a certain extent that may be true. But since chronic prostatovesiculitis produces in the spermatozoa morphologic abnormalities identical with those caused by focal infections in other parts of the body, we have come to feel that its chief harmful effect results from the action of a constitutional rather than a local mechanism.

While it has repeatedly been shown that one or another type of deficient nutrition can depress the fertility of laboratory animals, there is small reason to believe that the ordinary mixed human diet often has this effect except in cases in which it includes too little protein. Insufficient exercise causes a slowing down of the normal metabolic processes with results, for example lowered fertility and obesity, similar to those produced by metabolic underfunctions of endocrine origin.

Most of the causes of human infertility are due directly or indirectly to environment, and in particular to the artificial conditions of civilized life. One has come to recognize however, a small group of cases in which a hereditary tendency to low fertility, intensified by the accidental mating of individuals possessing that trait, ultimately results in the dying out of their stock. Thus may be explained the barrenness of certain marriages in which neither partner presents any demonstrable obstacle to reproduction. A family history of infertility should always be taken into consideration in formulating a prognosis.

This paper has given a summary of modern views on the fundamental nature of those adverse influences which make conception unlikely or impossible. The number and diversity of such factors indicate that complete diagnostic study is the only basis on which the best results of treatment can be obtained. A project of this sort requires group organization, in which the work of the urologist must be closely correlated with that of his associates in the fields of gynecology, internal medicine and endocrinology.

TESTICULAR BIOPSY

ITS VALUE IN MALE STERILITY

CHARLES W. CHARNY, M.D.

PHILADELPHIA

The ever increasing interest in the study of male infertility has stimulated investigation of spermatozoal physiology, semen abnormalities and the pituitary-gonadal relationship, but the microscopic study of testicular tissue, accessible as it is, has been neglected.

An important step in this direction was made by Huhner¹ in 1913, who advocated testicular aspiration as a diagnostic measure in instances of azoospermia. In the performance of this test, recovery of spermatozoa in the testicular aspirate connotes active spermatogenesis despite the absence of spermatozoa from the semen and indicates, by inference, the presence of obstruction in the seminal tract. While this procedure represents a step forward in the study of testicular spermatogenic function, it has its limitations. Irrespective of the caliber of the needle employed for the aspiration, it often happens that no secretion is obtained. Moreover, the specimen of testicular secretion may be devoid of spermatozoa only because the particular seminiferous tubules that were reached were relatively inactive, whereas in other tubules in close proximity spermatogenesis may be advanced. For these reasons, data derived from testicular aspiration are conclusive only if spermatozoa are recovered.

Even when spermatozoa are found, the value of testicular aspiration is limited to the differentiation between obstructive and nonobstructive azoospermia. Lesser faults in spermatogenesis leading to varying degrees of oligozoospermia cannot be investigated by this method.

In order to determine the actual state of testicular function it is necessary to adopt a procedure, such as testicular biopsy, which will allow direct microscopic observation of the seminiferous tubules. As its name implies, testicular biopsy consists of the operative removal of a piece of tissue from the testis, so small as to have no deleterious effect on the gland yet large enough to include a representative group of tubules. This was first performed experimentally by Engle and clinically by Hotchkiss.² The application of testicular biopsy to human beings has been generally limited to the differentiation of the two kinds of azoospermia previously mentioned.³

In this preliminary report I am privileged to emphasize the simplicity of the technic of testicular biopsy and to recommend its wider application in male infertility.

TECHNIC OF TESTICULAR BIOPSY

The technic of testicular biopsy is simple and can be performed in the office if strict aseptic technic is available.

The testis, with the scrotal skin taut, is held in the operator's left hand. After application of an antiseptic, a portion of the skin overlying the anterior surface of the testis is infiltrated with 1 per cent procaine hydrochloride. An incision about 1.5 cm. long is made through the skin and carefully carried through all the

fascial layers until the parietal layer of the tunica vaginalis is opened. This is signaled by the escape of serous fluid and the appearance of the glistening visceral layer of the tunica vaginalis. The latter and the tunica albuginea are nicked with a small scalpel. Gentle pressure on the testis now serves to extrude a small bead of tissue, which is cut off with a curved iridectomy scissors. The testicular incision need not be sutured. The skin is closed with two interrupted catgut sutures and a collodion dressing applied. The patient may return to his former duties the following day, a suspensory being worn for a day or two. The specimen of tissue is preserved in Bouin's solution, mounted in paraffin for section and stained by hematoxylin-eosin.

MICROSCOPIC APPEARANCES IN TESTICULAR BIOPSY

Examination of the normal histologic section reveals a number of seminiferous tubules surrounded by interstitial tissue containing the cells of Leydig. Each seminiferous tubule consists of a connective tissue basement membrane supporting a number of layers of specialized epithelial cells in different stages of sper-

Fig. 1 (case 1).—Normally functioning seminiferous tubules. The three zones are well illustrated. Reduced from a photomicrograph with a magnification of 250 diameters.

matogenesis. The deepest layer consists of cubical cells, which enlarge to form spermatogonia. Some of the spermatogonia may be observed in mitosis, forming two or three layers of large polyhedral cells, spermatocytes, which constitute the second zone. The spermatocytes further divide to form the third zone, a layer of small polyhedral cells, spermatids, each of which develops into a spermatozoon. In addition to these three layers there may be seen a number of elongated columnar cells, the cells of Sertoli.

It is not my intention to discuss the various pathologic states involving the seminiferous tubules that may be observed. Suffice it to state that they may be generally classified into two groups: those due to incomplete maturation, in which instance cell division stops at the first or second zone, and those caused by degenerative lesions in a fully matured tubule.

CLINICAL APPLICATION OF TESTICULAR BIOPSY

Since testicular biopsy gives the most direct evidence of the actual state of spermatogenesis, it may be utilized to great advantage in any instance in which a pathologic disturbance of the seminiferous tubules is

Read before the Section on Urology at the Ninety-First Annual Session of the American Medical Association, New York, June 14, 1940.

1. Huhner, Max: *Sterility in the Male and Female and Its Treatment*, New York, Rehnman Company, 1913. *Aspiration of the Testicle in the Diagnosis and Prognosis of Sterility*, *J. Urol.* 19: 31 (Jan.) 1928.

2. Engle, E. T.: Personal communication to the author.

3. Lane-Roberts, Cedric; Sharman, Albert; Walker, Kenneth, and Wiesner, B. P.: *Sterility and Impaired Fertility*, New York, Paul B. Hoeber, Inc., 1939.

suspected. It is especially valuable in male infertility under the following circumstances:

1. In azoospermia, to differentiate between the obstructive and nonobstructive types.
2. In oligozoospermia, to determine the severity of the pathologic process and to differentiate between faults in spermatogenesis and postinflammatory obstructive lesions of the ejaculatory ducts.

Fig. 2 (case 2).—Degenerative changes in the seminiferous tubules. Reduced from a photomicrograph with a magnification of 250 diameters.

genesis and postinflammatory obstructive lesions of the ejaculatory ducts.

3. As a prognostic gage, to observe the severity of the pathologic process and thus determine the capacity of the tubules to regenerate.
4. As a therapeutic gage, to evaluate by repeated biopsies the efficacy of the various extracts recommended for stimulation of spermatogenesis.

Accordingly, I have performed testicular biopsy on a series of forty infertile patients presenting various

Fig. 3 (case 3).—Immature seminiferous tubules. Central tubule shows failure of development of the third zone. Reduced from a photomicrograph with a magnification of 250 diameters.

types of semen abnormalities. No untoward reactions were encountered. While the number of patients is still too small to permit any generalizations, the value of the procedure in male infertility and the justification for its further application are well illustrated by the following sample case reports:

GROUP 1. REPORTS ILLUSTRATING THE VALUE OF TESTICULAR BIOPSY IN AZOOSPERMIA

CASE 1.—J. D., aged 29, had a small left testis and an indurated lower pole of the epididymis in an otherwise normal right testis. Semen examination revealed azoospermia. Testicular biopsy revealed failure of development of the seminiferous tubules on the left side. The right testis showed functioning tubules with normal differentiation of the lining epithelial cells (fig. 1). Epididymovasostomy was therefore performed on the right side. Microscopic examination of the secretion obtained from the upper pole of the right epididymis, during the course of the operation, revealed numerous spermatozoa, corroborating the observations of the testicular biopsy.

CASE 2.—J. R., aged 32, had had bilateral gonorrheal epididymitis. Physical examination revealed induration in the lower poles of both epididymides. Testicular aspiration yielded no spermatozoa on the left side and from 2 to 3 spermatozoa per high power field on the right. Testicular biopsy revealed poorly functioning tubules bilaterally, indicating that the semen would be deficient in spermatozoa even if the obstruction was relieved (fig. 2). Operation was not advised.

Without testicular biopsy it would not have been possible in these two cases to determine the state of spermatogenesis and the advisability of operation.

Fig. 4 (case 5).—Atrophy of the seminiferous tubules. Note normal appearance of cells of Leydig. Reduced from a photomicrograph with a magnification of 250 diameters.

GROUP 2. REPORTS ILLUSTRATING THE DIAGNOSTIC VALUE OF TESTICULAR BIOPSY IN OLIGOZOOSPERMIA

CASE 3.—B. F., aged 24, had had gonorrheal infection apparently cured before marriage. Physical examination was negative except for an indurated left seminal vesicle. Prostatic infection was present. Semen examination revealed a volume of 2.5 cc., 6,800,000 spermatozoa per cubic centimeter and 43 per cent abnormal forms. Testicular biopsy revealed failure of maturation of most of the tubules, indicating the need for stimulation of spermatogenesis (fig. 3).

CASE 4.—J. K., aged 42, had from 15 to 20 white blood cells per high power field in the prostatic secretion. The semen was very viscid and had a volume of 1.5 cc., a count of 1,200,000 spermatozoa and 12,000,000 white blood cells per cubic centimeter. Testicular biopsy showed actively functioning seminiferous tubules. It was therefore concluded that the reduction in semen volume and sperm count was due to ejaculatory duct obstruction occasioned by a long standing seminal vesiculitis. Treatment was therefore directed toward the elimination of the chronic infection.

As illustrated by both cases, testicular biopsy serves to differentiate between the obstructive and nonobstructive types of oligozoospermia. In the first instance (case 3) the oligozoospermia was proved to be the

result of faulty spermatogenesis as shown by the state of the seminiferous tubules (fig. 3). In the second instance (case 4) it may be inferred from the finding of normal testicular tissue that the oligozoospermia was obstructive in origin. I am firmly convinced that, in many instances, oligozoospermia is caused by ejaculatory duct atresia rather than faulty spermatogenesis.

GROUP 3. REPORTS ILLUSTRATING THE VALUE OF TESTICULAR BIOPSY AS A PROGNOSTIC GAGE

CASE 5.—M. L., aged 30, had had bilateral orchidopexy at the age of 16 for cryptorchism. Physical examination was negative. The semen showed azoospermia. Testicular biopsy revealed tubules lined by a single layer of undifferentiated cells and filled with acellular hyaline shreds, corroborating the clinical impression of irreparably damaged seminiferous tubules (fig. 4).

CASE 6.—T. M., aged 27, had had bilateral orchitis complicating mumps at the age of 19. Examination revealed testes of normal consistency but reduced in size. The semen had a volume of 4.5 cc. with 3,500,000 spermatozoa per cubic centimeter. Testicular biopsy revealed complete atrophy of the seminiferous tubules on the right side. On the left, islands of normally functioning seminiferous tubules were found inter-

Fig. 5 (case 6).—Islands of normally functioning tubules interspersed among completely atrophied tubules. Note persistence of cells of Leydig in the atrophied area. Reduced from a photomicrograph with a magnification of 250 diameters.

spersed among atrophied tubules (fig. 5). The impression gained from this observation was that the tubules which had escaped destruction were already functioning at full capacity and that further stimulation was useless.

It is obvious that no regeneration can be expected in seminiferous tubules that have undergone complete atrophy, no matter how effective the therapeutic agent may be.

GROUP 4. REPORTS ILLUSTRATING THE VALUE OF REPEATED TESTICULAR BIOPSIES AS A CRITERION OF THE EFFICACY OF THERAPEUTIC AGENTS

CASE 7.—O. D., aged 24, was normal except for an infected prostatic secretion. The semen volume was 2.5 cc., with 4,600,000 spermatozoa per cubic centimeter. The patient was given intramuscular injections of 400 international units of gonadotropic hormone of pregnant mare serum three times weekly for a total of 12,000 international units. Reexamination of the semen following treatment showed no improvement (a volume of 2.5 cc. and a sperm count of 4,300,000 per cubic centimeter). Comparison of the testicular biopsies performed preliminary, to and following the treatment, however, showed a definite improvement in the histologic picture of the seminiferous tubules (figs. 6 and 7).

COMMENT

The performance of testicular biopsy before and after a given form of therapy yields more direct evidence of the efficacy of that remedy than any other method in use at the present time. While repeated examination of the semen furnishes evidence of the degree of prog-

Fig. 6 (case 7).—Poorly functioning seminiferous tubules. Sperm count 4,600,000 per cubic centimeter. Reduced from a photomicrograph with a magnification of 250 diameters.

ress as a result of treatment, it is not an accurate yardstick because changes in the semen may occur which are produced by factors unrelated to the process of spermatogenesis. Reduction in the sperm count may, for instance, be produced by excessive frequency of coitus or by incomplete ejaculation resulting from the patient's difficulty in obtaining a specimen at an appointed time. Thus, an apparent increase in sperm population after a period of treatment may be merely

Fig. 7 (case 7).—Appearance after administration of 12,000 international units of gonadotropic substance of pregnant mare serum. Reduced from a photomicrograph with a magnification of 250 diameters.

the result of an improved method of collection of the specimen occasioned by repeated attempts.

On the other hand, increased cellular activity in the seminiferous tubules effected by therapy and demonstrated by testicular biopsy is true evidence of the effectiveness of the agent employed. Thus far I am subjecting only one product, gonadotropic hormone of

pregnant mare serum,⁴ to this critical investigation.

To date a total of five patients presenting varying degrees of faulty spermatogenesis, as judged by semen examination and testicular biopsy, were subjected to repeated testicular biopsies during the course of treatment. Each patient was given 400 international units of gonadotropic hormone of pregnant mare serum intramuscularly, three times a week for three weeks. Subsequent injections were administered intravenously thrice weekly for approximately two additional months, at which time a second testicular biopsy was done.

The observations on the five patients are summarized in the accompanying table. It is of interest to note that, although only three of the five patients showed an improved semen picture following the mare serum hormone therapy, all the patients presented histologic evidence of stimulation of the seminiferous tubules. These results, although limited to a small number of observations, are sufficient evidence to suggest that the administration of hormone of pregnant mare serum deserves further trial as a spermatokinetic agent.

Observation of the Spermatokinetic Effect of Gonadotropic Hormone of Pregnant Mare Serum in Five Infertile Males

Patient	Before Treatment		After Treatment		Changes in Tubular Activity as Observed by Testicular Biopsy
	Semen Volume in Cc.	Sperm Count per Cc.	Semen Volume in Cc.	Sperm Count per Cc.	
1. G. O.	2.5	16,400,000	3.5	29,600,000	Increased
2. D. M.	1.0	1,100,000	2.0	2,900,000	Increased
3. O. D.	2.5	4,600,000	2.5	4,300,000	Increased
4. J. B.	3.5	500,000	5.0	6,400,000	Increased
5. D. K.	3.5	10,100,000	3.0	29,000,000	Increased

CONCLUSIONS

1. Testicular biopsy is a simple, innocuous procedure as shown by its application in forty infertile patients without a single mishap.

2. Testicular biopsy is not only a definite diagnostic aid in differentiating between obstructive and non-obstructive semen defects but serves a prognostic function as well.

3. When performed before and after treatment, testicular biopsy yields the most direct evidence of the efficiency of the therapeutic agent employed.

1825 Pine Street.

ABSTRACT OF DISCUSSION

ON PAPERS OF DR. KREUTZMANN, DRs. MEAKER AND VOSE AND DR. CHARNY

DR. ROBERT S. HOTCHKISS, New York: Drs. Meaker and Vose exemplify what can be accomplished by team work between the two specialties of urology and gynecology. A complete history and careful general physical examination are as much a part of the examination of the husband as the semen studies. The new phrase "the inherent strength of the germ cell" is expressive. Not only do men differ greatly from one another in their state of fertility but certain men are particularly unstable and sensitive to adverse influences. A group of twenty-two men that I have studied for over a year demonstrates that those individuals who have unstable sperm counts are more apt to react violently to transient illnesses. The effect is not fully registered in the semen for from forty to sixty days. The clinical inferences are quite obvious. Dr. Charny's report on testicular biopsy promises much. This simple painless diagnostic procedure should be carried out as a preliminary step whenever doubt exists as to whether the azoospermia is due to asperma-

togenesis or occlusion of the seminal tract. Normal size and consistency of the testicle is no assurance that spermatozoa are being produced. If active and satisfactory spermatogenesis is observed in the section of the biopsy specimen and there is reason to believe that the obstruction is in the scrotal area there is no need for further diagnostic tests. Injection of the vasa with colored solutions does not test the usual and likely site of the obstruction, which is most apt to be in the globus minor of the epididymis. Furthermore, additional scar and occlusion may be produced at the site of the vasa puncture. If the biopsy specimen demonstrates grossly defective spermatogenesis, time and expense are saved. The knowledge of the endocrines as related to spermatogenesis is far from satisfactory. We have no entirely reliable, accurate and inexpensive tests to measure the functions of the ductless glands. Microscopic study of these testicular biopsies will ultimately allow one to predict which type of spermatogenic deficiencies will be amenable to endocrine stimulation. Should Dr. Charny's work lead to such an important advance, much of Dr. Kreutzmann's valid objection to indiscriminate treatment will be overcome. Second only to the importance of proper selection of the patient is the problem of maintaining patency at the site of the anastomosis. Drs. Draper, Kauer and I have recently undertaken a modification of the Martin operation designed to reduce or prevent postoperative stricture. Experiments on dogs convinced us that large gage silver wire can be left within the vas for weeks without producing important tissue irritation.

DR. MAX HUHNER, New York: As regards the criticisms of aspiration of the testicles with a needle, I have performed this simple procedure for over thirty years in scores of cases without any bad results. Nor have there been reported in medical literature any bad results by others. The objection made by Dr. Charny that I do not obtain material from several portions of the testicle does not hold in view of the fact that I do not simply stick the needle into the body of the testicle but insert it through the entire length of the testicle as well as the epididymis and continue the suction as I slowly remove the needle, so that I obtain samples from various portions of the testicle as well as from the epididymis. Such an objection would be more patent in testicular biopsy, as he obtains a specimen only from the small portion of the testicle just underneath his 1.5 cm. incision. I can see, however, that with the biopsy method much needed information can be obtained concerning the physiology and pathology of the testicles. I have not as yet done a testicular biopsy because I have obtained so much information from the simpler method of aspiration. By this method we can diagnose in any case of azoospermia whether the condition is due to occlusion of the genital tubes or to lack of spermatogenic function of the testicles or both. With my method I was the first to show as early as 1924 that an infection could be so slight as not to produce the characteristic nodules of an epididymitis but might still be severe enough to cause an occlusion of the genital tubes. Dr. Kreutzmann has covered the ground in an exhaustive manner. I am sorry that he did not mention the deleterious effect on the function of the testicle produced at times with the x-rays. If we do not think of this condition we shall not make the proper diagnosis, as the testicles feel perfectly normal; therefore the statement that when the testicles feel normal the lack of sperm is due to obstruction needs modification. Dr. Kreutzmann has very properly mentioned the condition of hypospadias as at times a cause of sterility. I wish to emphasize more fully than he did that the mere fact of a hypospadias being present, even if extreme, does not by any means indicate that that is the cause of the sterility. The only way one can diagnose this is by the postcoital or Huhner test, which, by the way, is a test for sterility in the male just as much as in the female. If after coitus one finds numerous spermatozoa in the female cervix one at once knows that a hypospadias, no matter how severe, has nothing to do with the sterility. Dr. Meaker and Dr. Vose for several years have covered the subject of sterility in all its aspects and have added much valuable information of their own. The most essential point which they have brought out is the value of group diagnosis especially as initiated and perfected by them.

4. Supplied by the Schering Corporation.

DR. HENRY SANGREE, Philadelphia: Fertility is a divided responsibility equally between the husband and the wife. To date the wife has been assigned most of the blame in a barren marriage. My investigations show that the male partner is at fault in about 50 per cent of childless unions. Team work should be present in a study of infertility and should include a gynecologic, obstetric, urologic, roentgenologic, endocrinologic and laboratory survey. The urologist by training and experience is particularly fitted to examine and treat the male partner in a sterile marriage. Between two and nine factors are often present in a study of both partners. In a study of the first hundred consecutive cases, among the congenital abnormalities were three cases of hypospadias, two cases of cryptorchism and four cases of Froelich's syndrome with atrophy of genitalia. Chronic prostatitis occurred in twenty-one. I consider this an important cause of the lowering of the fertility index and believe treatment should be given for this condition. The thick, viscid ejaculate and infective pus in a grade 1 to a grade 5 prostatitis appears to entangle and immobilize spermatozoa in the same comparative proportion that the viscid pus from a chronic endocervicitis causes sterility in the female. Epididymis-vasostomy has been done in 3 per cent of my cases with one success. Two of the men gave a history of scrotal trauma, one with a football injury and one during his work in a factory. In each of these cases a small threadlike vas was present on the side of trauma, and in the opposite side a small hydrocele was present of about 15 cc., not diagnosed preoperatively. Both had azoospermia and only a few mobile sperm were found in one of the cases at the operating table. An innovation in procedure was instituted in the last operation. The wife was also brought into the operating room, timed thirteen days after the beginning of her menstruation, which the gynecologists tell us is the optimum time, and artificial insemination was done before anastomosis, with sperm from the epididymis. Unfortunately this is without success to date. Impotence not only is the inability of insemination but includes failure of the erector mechanism. Two patients were successfully subjected to the impotence operation devised and perfected by Dr. Lowsley of New York. They were both hospitalized and were given a most thorough medical, endocrine and psychiatric preoperative examination. Endocrine investigation has made rapid strides in the last decade. It is deplorable that no simple practical test has been devised for the anterior lobe of the pituitary gland. The Fluhmann test in either the blood or the urine has not been satisfactory in my hands. Though not particularly emphasized to the present time, basal metabolism tests should be done as a matter of routine. Twenty-one cases of hypothyroidism occurred ranging from minus 5 to minus 42. The careful survey, group endeavor and treatment of both partners in childless marriages will lead to a greater percentage of successful results.

DR. W. W. WILLIAMS, Springfield, Mass.: I am interested in the emphasis which has been placed on azoospermia and aspermia, since the semen analysis of 110 consecutive cases from sterile matings in my series revealed only one case in which no spermatozoa were delivered. The low incidence of aspermia in this series is possibly because some of the patients avoided general sterility studies. There were others whose spermatozoa were so scarce that they were difficult to find, and the density of the spermatozoa or the count varied markedly through the whole series. It is often difficult to say just what is responsible for the deficiency of spermatozoa and the abundance of abnormal cells which occur in these samples. Out of a group of twenty-one cases in which the basal metabolic rate had been determined in addition to the studies on spermatogenic pathology, two were so deficient in spermatozoa that they could not be examined for pathologic changes. Of the nineteen which were examined, seven showed a minus basal metabolic rate of 10 per cent or below, and the other twelve a basal metabolic rate of higher than 10 per cent. The low group showed an average of 30 per cent pathologic cells and the more normal group 27 per cent, which in a small series of this kind would be fairly normal fluctuation. This does not in the least indicate that thyroid deficiency may not be a factor. In some of these cases there was a very low basal rate and possibly the thyroid was a factor in causing spermatogenic anomalies; but certainly it is not very well proved.

There is another point which has a bearing on the appearance of azoospermia: It was generally noted in this series that the rate of spermatogenesis was lowered in cases in which there were increased numbers of pathologic forms. As the rate of spermatogenesis diminished, the rate of formation of pathologic cells increased. Had the decreased number of spermatozoa in the semen occurred as the result of a stenosis of the passages, one would expect that the ratio of abnormal forms would not have been increased.

DR. HENRY A. R. KREUTZMANN, San Francisco: Some phases of sterility in the male can be diagnosed and treated only by the urologist. It is therefore most important that the urologist establish a thorough method of diagnosis and treatment in these cases. Dr. Hotchkiss's statement that the injection of a needle in the vas may produce stenosis at that point is well taken. I have had the opportunity in a number of cases to examine the vasa months after such injections had been made and have found that the lumen in no instance was occluded by the introduction of the needle. I feel that injection of the dyes is a simple and effective way of determining the patency of the vas, particularly when the needle is inserted as near the globus minor as possible. Infections of the vas deferens are much more common than is realized, as we showed in a paper on this subject presented before the American Urological Association in Minneapolis in 1937. The majority of the patients in whom cultures of the vasa were positive had no symptoms and the vasa appeared normal on gross examination, yet the lumen in many instances was completely blocked, preventing the passage of a silkworm strand. With regard to the number of cases showing no sperm, the number varied between 12 and 15 per cent. Sterility is an important subject for both men and women and I feel that in the future the urologist cannot perform all the necessary examinations himself, as there are too many factors involved. The ideal way of solving this problem and obtaining the best results is to have the urologist associated with a laboratory man who is conversant with studies of the sperm, a gynecologist and an endocrinologist.

DR. CHARLES W. CHARNY, Philadelphia: Two patients with oligospermia illustrate the value of testicular biopsy in sterility. The first had a count of 4,600,000 spermatozoa per cubic centimeter with a large percentage of abnormal forms. Microscopic examination revealed the poor differentiation of the epithelium lining the seminiferous tubules, corresponding to the defective sperm population. The second patient had a count of 2,300,000 spermatozoa per cubic centimeter with only 18 per cent abnormal forms but with evidence of marked adnexal infection. Microscopic examination disclosed more active spermatogenesis than the previous one, and yet the sperm count was actually lower, serving to support the theory that a great number of patients with low sperm counts in the ejaculate possess testes undergoing normal spermatogenesis.

DR. FRANCIS R. HAGNER, Washington, D. C.: Dr. Hotchkiss spoke of the use of a splint in the vas deferens. I don't believe that the vas deferens has anything to do with the failure in my cases when it is open at the time of operation. I believe that the trouble is in the cut tubules, and I have always felt that any foreign body left in situ for any length of time rather tends to form fibrous tissue and there is more chance of preventing this sinus forming between the cut ends of the tubules and the vas deferens. I am not opposed to it at all. I am going to try it, but that has just been my reaction to it as it has been done before. Dr. Huhner reported the single case in which the epididymis was punctured for examination, with a report of live spermatozoa being found. When I operated on the man while he had the small abscess, the other epididymis was absolutely structureless. It was red and looked almost like a piece of liver. I felt that possibly the introduction of the needle had some effect. That is the only case in which I have operated in which previous puncture had been done. I used dye at the time of operation early in my work. It might be all right to use it before operation, but at operation everything gets messed up with it and one can't make the tissues out as well. So I gave it up at the time of operation. I also feel that if the occlusion in these patients is farther up than one can get a silk gut probe, one can't do anything for those cases in the operative procedure from the lower end.

ASTHMATIC BRONCHITIS FOLLOWING CHRONIC UPPER RESPIRATORY INFECTION

A FIVE YEAR STUDY OF 235 CONSECUTIVE CASES
SEEN IN PRIVATE PRACTICE

LEE BIVINGS, M.D.

ATLANTA, GA.

In the presentation of this material I do not wish to disparage the study of bronchitis of allergic origin but to call attention to the frequency of chronic infection of the upper respiratory tract especially when accompanied by bronchitis with wheezing, which is subsequently referred to as asthmatic bronchitis. This clinical entity occurs frequently in pediatric practice and I shall attempt to define it and to show that it is primarily an infectious process. In a review of recent medical literature¹ and in textbooks² it seems to be considered a part of asthma, but while it may occur in the asthmatic child it would seem distinct and different from allergy unless bacterial hypersensitiveness may be considered an allergic phenomenon.

Any group of symptoms which distinctly impair the health of the child certainly should be honored as a

Fig. 1.—Infiltration of right upper lobe, February 19.

Fig. 2.—Little change in right upper lobe, February 22, with increasing reaction in left lower lobe.

Fig. 3.—Considerable clearing of infiltration, February 27, leaving behind a peribronchial reaction and a number of discrete glands.

clinical entity. When chronic upper respiratory infection becomes severe enough to cause the following symptom complex, it has attained the classification of a definite disease:

SYMPTOM COMPLEX

The symptom complex which occurs almost exclusively in winter, consists of:

1. Cough, often paroxysmal in character, resembling whooping cough, occurring usually in the early morning or when retiring, rarely during the day unless after severe exertion.
2. Malodorous breath, especially in the morning.
3. Anorexia and loss of weight.
4. Recurring colds.
5. Abdominal pain and nausea.
6. Profuse night sweats (not present in all cases).
7. Bronchitis, frequently unilateral, more likely to occur if the condition has existed for some time.

Physical examination reveals that:

1. The child appears anemic and suffering from malaise.
2. Fever is usually present to a slight degree.
3. The nasal mucosa is engorged and red with a coating of mucopurulent secretion. Frank pus is often seen in the floor of the nasal passages.
4. The tongue is heavily coated.

Read before the Section on Pediatrics at the Ninety-First Annual Session of the American Medical Association, New York, June 12, 1940.

1. Mitchell, A. G., and Cooper, M. L.: *Vaccine Treatment of Asthma in Childhood*, Arch. Pediat. 48: 751 (Dec.) 1931.
2. Griffith, J. P., Crozer, and Mitchell, A. Graeme: *Diseases of Infants and Children*, Philadelphia and London, W. B. Saunders Company, 1937, p. 691.

5. The pharynx is red with islands of lymphoid tissue appearing prominently. A mass of mucopurulent material is often seen behind the soft palate.

6. Resistance to pressure is often found in the right upper quadrant of the abdomen.

Laboratory examination reveals:

1. Severe secondary anemia present in almost all cases and often as low as 45 per cent (Newcomer).
2. A slight rise in the total white cell count and a slight increase in the relative neutrophil count.
3. Usually absence of eosinophils in increased amounts on nasal smears stained with Wright's stain.
4. Usually pure culture of streptococci or staphylococci or a mixed growth of these two organisms on culture of the nasopharynx.

ASTHMATIC BRONCHITIS

During the first few years of life attacks of bronchitis are often accompanied by wheezy respiration and the physical signs characteristic of asthma. Attacks of this kind are often spoken of as "asthmatic bronchitis."³

They differ from asthma:

1. In being continuous rather than paroxysmal.
 2. In the constant presence of a local infection.
 3. In the failure to respond satisfactorily to epinephrine.
- Allergy seems to play little part in their production.

Specific sensitiveness cannot be demonstrated. Nor is there eosinophilia.

BACTERIOLOGY

Cultures taken from the nasopharynx by sterile loop and grown in bouillon incubated over twenty-four to forty-eight hours and stained with Gram's stain or grown on blood agar yielded streptococci (viridans and hemolytic) thirty-eight times, staphylococci (aureus and albus) nineteen, catarrhalis four, staphylococci and streptococci ten, streptococci and pneumococci once and a gram-negative rod once; total, seventy-three.

EFFECT OF TONSILLECTOMY

Operations for removal of tonsils and adenoids had been done in 30 per cent of the cases; it would seem that the operation has no beneficial effect on the course of the infection or in preventing recurrences.

INFLUENCE OF SEX

There were 110 girls and 125 boys.

COMPLICATIONS

Asthmatic bronchitis occurred in approximately 35 per cent.

Otitis media was present in approximately 3 per cent.

3. Holt, L. Emmett, and Howland, John: *Holt's Diseases of Infancy and Childhood*, revised by L. Emmett Holt Jr. and Ruskin McIntosh, ed. 10, New York and London, D. Appleton & Co., 1933, p. 754.

Recurrences were experienced in seventy-one cases, or 30 per cent.

TREATMENT

1. *Supportive.*—A generous diet was prescribed, with cod liver oil, increased rest and definite treatment of the anemia. This seemed best accomplished by oral administration of from 6 to 9 grains (0.4 to 0.6 Gm.) of crystals of ferrous sulfate in a vehicle (elixir) of thiamine hydrochloride containing 250 units per teaspoon.

2. *Local Treatment.*—Nasal tampons of 1 per cent ephedrine were used for ventilation and drainage. In some instances in which the discharge was profuse, a Sonderrmann suction pump was used twice daily at home by the mother.

3. *Foreign Protein Therapy.*—Autogenous vaccines were first used and abandoned because the results did not seem to justify the increased cost to the patient. It is also probable that the bacterial count was too low. Stock vaccine (mixed) of a very high count was then used with a high percentage of good results. In the last few months I have been taking cultures in every case and using a mixed autogenous vaccine of a high count which matched the culture of a given case. For instance, if the culture showed streptococci, a streptococcus vaccine was given in a dosage of 0.2 cc., increasing 0.1 cc. each dose to a maximum of 1 cc. at three day intervals for the first four doses and weekly intervals for a total of from six to ten doses. Staphylococcus toxoid (No. 2 dilution) was used in some instances of staphylococcal infection.

4. *Chemotherapy.*—Sulfanilamide proved useful in the acute cases of asthmatic bronchitis but seemed valueless in the chronic infection.

RESULTS

The child usually remains relatively free from infection for months and sometimes years. A few children do not respond to treatment.

CONCLUSIONS

It would seem that the problem of treating these children is far more than one of local nasal treatment but one of deficient immunity with subsequent ill effects on the well-being of the whole body. All these factors must be considered in restoring the child to a normal state of health. The frequency of occurrence, the wintertime incidence, the presence of fever, the constant presence of infection, the absence of eosinophilia and the response to specific vaccine therapy would seem to entitle this clinical syndrome to a place of its own in pediatric practice, making it amenable to the care of any pediatrician and separating it from the field of allergy except when it occurs in the asthmatic in spite of the asthma and not because of the asthma.

REPORT OF CASE

The following brief summary of the history and physical examination,¹ with three roentgenograms, illustrates some of the characteristics of asthmatic bronchitis:

Barbara D., seen in February 1940, aged 4½ years, complained chiefly of wheezing and fever. Asthma had been present in a grandmother and an uncle. The tonsils were removed in 1938. The patient had pneumonia in 1938 and 1939 similar to the present illness. Physical examination revealed congestion in the nose, moist rales over both lungs posteriorly and the right upper lung anteriorly. There was an expiratory wheeze. Laboratory examination revealed hemoglobin 83 per cent, red blood

cells 5.08 million and white blood cells 11,500 with 73 per cent polymorphonuclear neutrophils. The urine was normal. A tuberculin test was negative.

COMMENT

The history of repeated pneumonias is common. The history of allergy in the family is not common. The onset with a cold, fever and wheezing is common. The physical signs are characteristic. The blood picture of an increase in the total white count of moderate degree and slight rise in the neutrophil count is the usual finding. The negative tuberculin test is important, since there is often suspicion of tuberculosis, so reported by the roentgenologist. X-ray examination February 19 (fig. 1) showed infiltration of the right upper lobe. February 22 (fig. 2) there was little change in the right upper lobe and an increasing reaction in the left lower lobe. This may have been a tuberculous pneumonia. By February 27 (fig. 3) the infiltration had cleared considerably leaving behind a peribronchial reaction and a number of discrete glands. "I still feel that this was a tuberculous pneumonia" (roentgenologist's opinion).

These roentgenograms illustrate the changing position of the pathologic condition in the lungs so often seen in asthmatic bronchitis, the most common location being in the left lower lobe posteriorly, where the bronchitis is characteristically unilateral.

The peribronchial reaction is also characteristic and often results in a roentgenographic diagnosis of juvenile or childhood tuberculosis.

20 Fourth Street N.W.

ABSTRACT OF DISCUSSION

DR. HAL M. DAVISON, Atlanta, Ga.: All children showing the syndrome described by Dr. Bivings should be treated as he has suggested. If the treatment is not successful, the patient should undergo thorough allergic study. No one, seeing the work of Jackson in Philadelphia, would doubt that there is some relation between bronchiectasis and chronic bronchial infections and infections in the sinuses. Wolf and others have shown that there is a definite drainage from the sinuses into the bronchial and mediastinal lymph nodes, so we cannot argue the relationship between infection in the upper respiratory tract and infection in the lungs. Among adult asthmatic patients the presence of chronic sinus infection detracts from their chances of relief, and x-ray treatment sometimes gives the only relief that can be produced. I have seen a few cases of asthma in children relieved by x-ray treatment for enlarged mediastinal nodes, after other treatment had failed. On the other hand, among both children and adults, numbers of cases apparently infectious do not improve until treated for allergy, and, after definite allergic treatment has been carried out, the infection disappears. No one can explain just why 35 per cent of Dr. Bivings's children should wheeze and 65 per cent should not wheeze. There must be a definite difference between such groups. Allergic sensitivity cannot be demonstrated in all these cases of wheezing, but that does not mean that it is not there. I have seen some adults with seasonal fall hay fever who give no positive cutaneous reactions yet obtained perfect results from ragweed pollen extract and have recurrence of symptoms if not so treated. The absence of eosinophilia is of little help in diagnosis here. Piness of Los Angeles, Bray of London, and Kern and Crompton of Philadelphia have presented results of research on the confusing pictures certain allergic syndromes in children offer in resembling pneumonia, and the resemblance of certain initial mucosal changes of infection to those of allergy. Therefore, since we frequently cannot determine whether these children are allergic, whether they are allergic to the infection or to something else, it seems that individual indications would be the logical procedure of handling.

DR. WARREN QUILLIAN, Coral Gables, Fla.: The symptom complex described by Dr. Bivings and classified under the title of asthmatic bronchitis occurs frequently in pediatric practice.

¹ By courtesy of the Eggleston Hospital for Children.

A recent review of about 2,000 case records in the lower coastal region of Florida indicates that 47 per cent of this series consists of respiratory infections (Quillian, W. P.: *Respiratory Infections*, *J. Pediat.* 15:704 [Nov.] 1939). Many children, brought to this resort center during the winter months in an effort to avoid sudden extremes of temperature, continue to have mild infections of the upper respiratory tract. But a large percentage of these patients who have previously experienced successive attacks of asthmatic bronchitis as a complicating factor find relief. The combined clinical experience of several pediatricians in this area confirms this impression emphasized by the author today concerning the predisposing effect of cold weather. Chronic disease of the paranasal sinuses is often discovered in this clinical syndrome. It is possible that constant absorption from such a low grade focal infection may create a bacterial allergy. The mucopurulent material may drip into the pharynx and by continuity of tissue involve the lower respiratory tract. There seems to be a lowered immunologic response among these patients. A high incidence of allergy in the family history makes one feel that there is an altered constitutional make-up. Otherwise, more children with chronic upper respiratory infections would develop asthmatic bronchitis. There is no substitute for careful physical examination. Permanently good results from therapy may depend on careful elimination of predisposing factors. In the use of autogenous vaccines one should bear in mind the changing bacterial flora of the nose and throat. A vaccine which is effective this year may require modification the next. All supportive measures designed to create a normal immunity to infection may be worthy of trial in the individual case. My experience confirms the belief expressed by the author that asthmatic bronchitis is a distinct clinical entity. The results from therapy have too often been a temporary amelioration of symptoms without permanent relief from the syndrome.

DR. HARRY LOWENBURG JR., Philadelphia: Dr. Bivings stated that the vaccine which he prepared contained 4 billion organisms in each cubic centimeter. In the past two years I have had occasion to take cultures of the nose and throats of more than a hundred children with chronic sinus infections, many of them associated with asthmatic conditions. In only three of these children did I get a pure culture, and in the subsequent production and administration of the vaccine I found that those children who had an associated asthmatic condition could not tolerate a dose of much more than 5 million organisms at the start of the course of injections. These children would receive severe local and occasionally general reactions even with such small doses. It has been my custom to have the vaccine made up with 500 million organisms to the cubic centimeter and give about a million organisms as an initial dose. The method of preparation of the vaccine that I have used was taught to me by Dr. Cooper at the Children's Hospital in Cincinnati. The individual organisms obtained are made into a separate vaccine. The patient is then skin tested with a small dose of each organism and, depending on the reaction obtained in twenty-four hours, the combined vaccine is prepared directly in proportion to the severity of the reactions. It has been my experience that those children giving the more severe reactions to the cutaneous tests derived the greatest benefit from the injections. There has been mentioned this morning the factor of undernutrition in these children. I have noticed that many of these children, instead of being undernourished, are on the obese side, and have found that with reduction in weight their general resistance has seemed to improve a great deal.

DR. FRANK LEE BIVINGS, Atlanta, Ga.: I want to emphasize two main points with regard to this study: First, that chronic upper respiratory infection in children is a very frequent occurrence; second, that asthmatic bronchitis primarily is infectious in origin, although there may be an allergic background which is a complicating or in some instances a predisposing factor. But it seems to me that asthmatic bronchitis as a clinical entity must be considered a bacterial infection and treated as such. Dr. Quillian brought up a point with regard to changing bacterial flora. I have not gone quite far enough yet to have definite data on that subject, but in some of the children on whom I have made bacteriologic studies I have found that one time they may have a streptococcal infection predominating and in the next instance a catarrhalis or some other type of infec-

tion. Therefore the autogenous vaccine and culture preceding each treatment would seem to be indicated. My experience has not been the same as Dr. Lowenburg's in regard to bacterial count. My vaccine was begun with low counts and the results were not entirely satisfactory, and for that reason the counts were increased. If one remembers that pertussis vaccine, on which so many rely, has a count of 20 billion to the cubic centimeter, one need not fear severe reactions in these children. I have not seen reactions occur after the first dose, except in unusual instances. I usually start them with about 0.25 cc. of a 6 to 8 billion count. In this study I tried to simplify the bacteriologic studies as much as possible. I did not go as far as Dr. Lowenburg said he had, because I am doing private practice and have to do these things as simply as possible. With the cooperation of the Emory University Department of Bacteriology I have worked out a technic by which I thought I could get good clinical results without having to go into detailed bacteriologic studies. For that reason I culture and grow the predominating organism and try to identify it as simply as possible and use that vaccine. My experience with regard to nutrition in these children is different from that of Dr. Lowenburg. I think he has in mind the asthmatic child rather than the asthmatic bronchitis child, because in those that I have seen the nutrition certainly had been far below normal in almost every instance, and one of the most noticeable clinical improvements is the rapid gain in weight that these children get after they have been treated.

INTRAMURAL POSTGRADUATE EDUCATION IN OBSTETRICS AND PEDIATRICS

FOR PRACTICING PHYSICIANS, FINANCED IN WHOLE OR IN PART FROM FUNDS APPROPRIATED BY CONGRESS FOR MATERNAL AND CHILD HEALTH SERVICES

EDWIN F. DAILY, M.D.

Director, Maternal and Child Health Division, U. S. Children's Bureau
WASHINGTON, D. C.

Short clinical postgraduate courses in obstetrics and pediatrics have been established by several state health departments in cooperation with medical schools and hospitals with teaching services. These courses have been developed for practicing physicians who wish an opportunity to observe and learn of the most recent advances in obstetrics and pediatrics. Where postgraduate courses had already been established the health departments have occasionally provided stipends or tuition or travel to assist physicians otherwise unable to attend the courses. These short courses are not designed to prepare physicians to become specialists in obstetrics or pediatrics.

Of the maternal and child health funds \$138,984 has been budgeted by the state health agencies for intramural and extramural medical postgraduate education in obstetrics and pediatrics during the fiscal year ending June 30, 1941. This amount may include for different states either the salaries of instructors or stipends; tuition or travel for the postgraduate students.

The U. S. Children's Bureau, in approving the plans submitted by the states for this purpose, has felt that efforts to improve medical education are one of the most important parts of any program endeavoring to improve the health of mothers and children.

A brief summary of the courses financed in whole or in part from the social security funds is presented here for the benefit of physicians including obstetrics or pediatrics in their practice who may wish to attend such courses.

Courses in Obstetrics and Pediatrics

School	Length and Content of Courses	Date When Courses Begin	Number of Students Accepted for Each Course	Physicians Eligible	Registration Fees and Tuition	Approximate Cost of Room and Board	For Application Forms and Detailed Information, Write to
University of California, San Francisco	One week obstetrics, two weeks pediatrics	Obstetrics, Dec. 16, 1940, June 2, 1941; pediatrics, Jan. 6, 1941, May 19, 1941, June 16, 1941	15	Physicians participating in state maternal and child health programs in California, Arizona, Nevada, New Mexico, Utah	\$10 registration fee and \$80 tuition (paid by respective state departments of health)	\$11 to \$12.50 per week	The director of maternal and child health in state health department of California, Arizona, Nevada, New Mexico, or Utah
University of Chicago, Chicago	Five weeks obstetrics only	Aug. 26, 1940, Oct. 7, 1940, Nov. 11, 1940, every five weeks in 1941	5	Graduates of accredited medical schools	\$25 registration fee; \$10 returned on completion of course	\$16 per week	Chief, Division of Child Hygiene, State Department of Public Health, Springfield, Ill.
University of Illinois, Chicago	One week obstetrics and pediatrics combined	Summer months only	18	Physicians practicing in Illinois	\$10 registration fee	\$15 per week (state health department pays for room, board, and travel expenses not exceeding \$25 for a two weeks course)	Chief, Division of Child Hygiene, State Department of Public Health, Springfield, Ill.
	Two weeks obstetrics and pediatrics combined	Arranged on application	4	Physicians practicing in Illinois	\$10 registration fee		
Indiana University, Indianapolis	Two weeks obstetrics	Nov. 4, 1940, Jan. 13, April 14, July 7, 1941	6	Graduates of accredited medical schools (preference to physicians practicing in Indiana)	\$10 registration fee (refunded on completion of course)	Board and room on campus paid for by Indiana State Board of Health for Indiana physicians	Director, Bureau of Maternal and Child Health, State Board of Health, Indianapolis, Ind.
State University of Iowa, Iowa City	One week obstetrics	Alternate weeks Sept. 23, 1940, to June 28, 1941	3	Graduates of accredited medical schools in the United States under 55 years of age	None	\$10 to \$20 per week	Director, Division of Maternal and Child Health, State Department of Health, Des Moines, Iowa
Tulane University of Louisiana, Louisiana State University, New Orleans	Two weeks pediatrics	Not available	10	Planned primarily for Louisiana physicians; others may be accepted	\$75 tuition, paid by Louisiana State Board of Health for Louisiana physicians	\$26 per week paid by Louisiana State Board of Health for Louisiana physicians	Director, Division of Maternal and Child Health, State Board of Health, New Orleans, La.
	Two weeks obstetrics	Not available	8				
Tufts College Medical School, Boston	One week or one month; separate courses in pediatrics and obstetrics	Not available	Not available	Graduates of accredited medical schools in the United States	Tuition and registration fees paid by Bingham Foundation for Maine physicians	A stipend is paid by Maine State Department of Health	If resident of Maine, State Department of Health and Welfare, Augusta, Maine
Harvard School of Public Health, Boston	Four weeks, two days each week, pediatrics Four weeks, one day each week, obstetrics	Not available	4	Limited to physicians conducting child health conferences and antepartum clinics in Massachusetts	None	Not available	Director, Division of Child Hygiene, State Department of Public Health, Boston, Mass.
University of Minnesota, Minneapolis	One course of six days	Oct. 11, 1940	30 to 50 for each course	Physicians practicing outside Minnesota	\$3 registration fee applies on \$25 tuition for six day course and on \$15 tuition for the three day course	\$15 to \$18 per week; room, board and travel paid by state health department of Minnesota and North Dakota for physicians they select	If residents of Minnesota or North Dakota, respective state health departments; otherwise, to director of postgraduate medical education, University of Minnesota
	Two courses of three days each in the spring of 1941			Physicians practicing in Minnesota		\$14 per week	
University of Nebraska, Omaha	Two weeks obstetrics and pediatrics combined	Jan. 6, Jan. 20, Feb. 3, Feb. 17, March 3, March 17, March 31, May 19, 1941	4	Graduates of accredited medical schools	\$10 registration fee (refunded on completion of course)		Director, Division of Maternal and Child Health, State Department of Health, Lincoln, Neb.
Columbia University, New York Post-Graduate Medical School, New York	One month (three days each week)	November, December 1940, February, March, May, and June 1941	5	Graduates of accredited medical schools	\$40 per month tuition	\$10 to \$15 per week	If residents of New Jersey, Consultant, Bureau of Child Hygiene, State Department of Health, Trenton, N. J.
Columbia University, given at Margaret Hague Maternity Hospital, Jersey City, N. J.	Three months obstetrics	First day of each calendar month	2 each month	Graduates of accredited medical schools	\$25 registration fee; applicable on tuition of \$350	Full maintenance in hospital included in tuition	If residents of New York, Director of Division of Maternity, Infancy and Child Hygiene, State Department of Health, Albany N. Y.
Duke University, Durham, N. C.	One week pediatrics and obstetrics combined	Not available	5 or 6	General practitioners in North Carolina in practice at least three years	\$15 registration fee (returned on completion of course)	\$12 to \$13 per week paid by North Carolina State Board of Health	Director, Maternal and Child Health Services, State Board of Health, Raleigh, N. C.
University of Oklahoma, Oklahoma City	Two weeks obstetrics	Not available	4	Graduates of accredited medical schools	\$25 registration fee (\$10 refunded on completion of course)	\$8 to \$12 per week	Division of Maternal and Child Health, State Health Department, Oklahoma City, Okla.
Baylor University, Dallas, Texas	Four weeks obstetrics and pediatrics combined	Not available	20	Licensed physicians practicing in Texas, preference to age groups 25-55 in communities of less than 25,000 population	\$50 tuition paid by state health department for physicians of their selection	\$30 per week; maintenance paid by state health department	Director, Division of Maternal and Child Health, State Department of Health, Austin, Texas
University of Texas, Galveston	Four weeks obstetrics and pediatrics combined	Not available	20				
University of Michigan, Ann Arbor	Two weeks obstetrics	Every two weeks	4	Licensed physicians practicing in Michigan	None	\$10 per week	Director, Bureau of Maternal and Child Health, Michigan Department of Health, Lansing, Mich.
Wayne University, given at Children's Hospital, Detroit	One month pediatrics	Every month	1	Licensed physicians practicing in Michigan	None	\$50 per month	

PREVENTION AND TREATMENT OF
DECUBITUS IN FRACTURES

THEODORE A. FOX, M.D.

AND

GEORGE L. APFELBACH, M.D.

CHICAGO

Decubitus is a major problem of a fracture service having an annual turnover of 1,400 patients. In spite of prophylaxis, its incidence is such that it frequently overshadows the original surgical condition requiring hospitalization. Bedsores often prevent open reduction.

The foreign and American literature offer little truly investigative work regarding etiology or prophylaxis. We here report a newly developed technic in the prophylaxis and treatment of decubitus.

A series of 232 cases were followed over a period of three months. The average age was 51 years. There were seventeen patients with fractured hips, from 60 to 95 years old, ten who were diabetic, six with fractured pelvis, and one who had a compression fracture with paraplegia. Of the original fifty-five patients six had

Fig. 1.—Group of patients treated by former accepted methods.

simple decubitus while twenty had deeply necrotic bedsores (chart 1).

Pressure is recognized as the chief cause of decubitus. It occurs usually over the sacrum, buttocks and heels, and less commonly over the malleoli, greater trochanters, scapulas and elbows. Pressure also occurs at the upper and lower edges of casts and at the ring of a Thomas splint. Trauma may be a contributing factor, caused by friction from bedclothes, rucks in sheets or dressings, gritty dusting powder or plaster, bedpans or other features of nursing care. Moisture, as in perspiration, urine or feces, macerates the skin and allows the entrance of infection. Senility, with its associated atrophy of the skin, is also a predisposing factor. Pressure areas due to lack of muscular development are more common in women. The skin of the Negro is less susceptible to decubitus. Hypovitaminosis is likewise a predisposing factor. Anorexia, poor dentures and associated dietary deficiency are common in the aged. The malnutrition and hypovitaminosis of alcoholic patients are well recognized. Hypoproteinemia with edematous skin, dehydration and chronic shock are frequently associated factors. Incontinence of urine or feces is com-

monly encountered, especially in the aged, and cord injuries lead to trophic disturbances with resulting infection. An increased incidence of bedsores in disease of the pancreas is recorded.¹

Love² classifies bedsores as follows: stage 1 (threatened), with generalized redness of the skin which blanches readily and immediately reappears when the pressure is released; stage 2 (inevitable), with increased redness which assumes a purple hue, pressure causing no blanching. Early a vesiculation occurs over the purple-red area. These small vesicles and blebs soon break, close scrutiny being required to discover them. The resulting weeping surface is ideal for infection. This stage passes into stage 3 (ulceration), with sepsis and toxic absorption.

We observed that these pressure areas resemble the blebs and vesicles of a second degree burn. Latimer³ also records this fact. In burns the skin is injured by thermal trauma with local edema and bleb formation. Decubitus pressure, from body weight or cast, causes dilatation of subcutaneous vessels and increased irritability of vasomotor endings in the skin; this results in the initial erythema with ready blanching on pressure. With continued pressure there is vasomotor paralysis and stasis. This accounts for the purple color and failure of the tissues to blanch on pressure, which in turn produces local edema and bleb formation.

Decubitus causes little pain, at least after the first day, probably owing to a pressure palsy of sensory fibers and to edema of the skin. With proper treatment only the first two stages should occur. Lesions in our cases never reached the stage of ulceration.

In the treatment of decubitus, prophylaxis is of the utmost importance. The breaking down of the skin must be avoided. With this in mind a "calamine varnish,"⁴ a mechanical and pharmaceutical aid, was developed. All pressure points are washed with tincture of green soap, alcohol and ether. The calamine varnish is applied with a brush and allowed to dry. Ordinary photographer's rubber cement is then spread over the same area and allowed to dry. These form a thick elastic coat over the points of pressure. The soothing astringent antiseptic coat, with its protecting layer of rubber, forms a pressure-proof, bacteria-proof, moisture-proof prophylaxis for decubitus. This is a routine procedure in the fracture ward. It may be repeated as often as necessary. It prevents the breakdown of tissue.

With urinary incontinence a Pezzar or Foley-Alcock⁵ catheter affords constant drainage. Frequent or continuous⁶ irrigation with 1 per cent phosphoric acid solution (to prevent alkaline cystitis) or alternately with 1:5,000 potassium permanganate solution should be given. We give ammonium mandelate or methenamine with sodium biphosphate for those intolerant to the former.

With male patients⁶ a funnel made of cellophane, rubber, or other moisture-proof material is fitted over the penis and connected by tubing with a drainage bot-

4. Tragaeanth 2 per cent, benzoic acid 1 per cent in Ringer's solution to make 100 per cent. Add to this prepared calamine N. F. 7.5 per cent and bentonite 2.5 per cent. The calamine and tragaeanth are well known emollients. The bentonite is a mildly antiseptic astringent aluminum silicate clay and the benzoic acid a preservative.

5. With a two way catheter, irrigation can be continuous by the gravity method with a screw clamp control.

6. Suggested by Dr. Frank Kelly, resident, Fracture Service, Cook County Hospital.

tle, preventing the severe urethritis of males so frequent with indwelling catheters. For anorexia and malnutrition, 5 units of insulin is administered subcutaneously one-half hour before meals. Fluids, usually from 3,000 to 5,000 cc. daily by mouth, are given in a routine manner or physiologic solution of sodium chloride or saline-dextrose solution is administered parenterally. The puffy red dry fissured tongue of dehydration is watched for. The benefits of a high vitamin diet, brewers' yeast, orange juice and cod liver oil become readily apparent by comparison with the control group (chart 2).

Careful observation of the patient's skin is essential. Should vesicles or macerations appear they are immediately debrided and sprayed with a 10 per cent solution of tannic acid and 1 per cent salicylic acid.⁷ When dry⁸ a 10 per cent solution of silver nitrate is painted over the area. This forms a black supple thin tough crust which gives a "new skin" surface and requires no further treatment.⁹ With infection and necrosis, fresh diluted solution of sodium hypochlorite is used freely. We do not cauterize exuberant granulations. This only adds a necrotic crust to a clean surface. A razor trims

Fig. 2.—Group of patients treated with the calamine varnish and liquid rubber or tannic acid method.

the overgrowth of tissue to the level of the skin surface. Epithelium can then bridge the gap.

Since recovery in the twenty original cases, there have been no deep ulcerations. When clean they are treated as described. Skin grafts may be necessary. There was only one instance in our series. Latimer³ describes the use of tannic acid in the treatment of necrotic decubitus and this method has been used by Love,² Spiesman,¹⁰ Cope¹¹ and many others. Nayarac and Morel¹² described the use of 5 per cent silver nitrate to stiffen the skin in early lesions. Proper application of prophylaxis, as outlined, should in most instances prevent decubitus with fractures and chronic illness. With the simple treatment here outlined the existing bedsore readily heals. The prognosis of decubitus is improved. Patients requiring surgical therapy need not forego its benefits because of bedsores.

FAILURE OF GELATIN OR AMINO-ACETIC ACID TO INCREASE THE WORK ABILITY

OF INDIVIDUAL NORMAL HUMAN MUSCLES

GEORGE L. MAISON, M.D.

DETROIT

The observation that gelatin was an effective agent in postponing human fatigue was made by Ray and his co-workers¹ in a now widely publicized paper which appeared in February 1939. To date no confirmation of this action of gelatin has appeared. Ray theorized that gelatin postponed fatigue by an action on the muscles themselves. He reasoned that creatine was a substance important in muscle chemistry, one of whose precursors in the body may be aminoacetic acid (glycocoll, glycine). Aminoacetic acid makes up 25 per cent by weight of gelatin. An added supply of aminoacetic acid was thought to increase the store of creatine in the muscles. If this is the mechanism by which gelatin acts, the effect should show up in increased work ability of a single human muscle during a period of gelatin or aminoacetic acid ingestion. Further, if gelatin has any action on fatigue its ingestion should increase the ability of individual muscles to do voluntary work, since the work of a single muscle requires cooperation of the circulatory, muscular and nervous systems just as does action of the body as a whole.

Experiments were therefore undertaken to test the work ability of a single human muscle before, during and after the ingestion of gelatin or aminoacetic acid.

METHOD

Male subjects fatigued the extensor digitorum communis muscle daily by doing work at a uniform rate. (The load was constant and the length and rate of contraction were constant.) Fatigue was defined as that condition in which the subject could not maintain the rate of work. In order to differentiate the ability of the neuromuscular system alone from the ability of the combined neuromuscular and circulatory systems, the right arm of each subject did its daily work without blood supply whereas the left arm retained its circulation during work.

A weight ergograph was designed especially for the extensor of the fingers.² The ergograph recorded on automatic counters the total distance through which the weight was moved and the total number of individual strokes made. A buzzer was included in the machine and contacts were so arranged that when the load was lifted to a set height the buzzer sounded. The subject was trained to lift the weights until the buzzer sounded and then to relax. Thus the strokes made were of nearly uniform length, about 6 cm. This is a comfortable stroke for the extensor if the metacarpophalangeal joint is used as a fulcrum, and the load is applied over the distal halves of the second phalanges of the fore, middle and ring fingers.

The definition of fatigue mentioned was made possible by the buzzer. The subject makes one contraction per second. When he can no longer ring the buzzer in the allotted time he ceases to work.

The blood supply to the muscle of the right arm was interrupted during its work by means of a sphygmomanometer cuff

instantaneously inflated to a pressure of 240 mm. of mercury from a pressure reservoir of about 5 gallon capacity. Muscles worked under this condition are hereafter referred to as "ischemic."

RESULTS

The experiments were divided into two groups: The first group shows the effect of gelatin on muscles in the process of rapid training. This is analogous to Ray's procedure, since his subjects had trained for only thirty days before gelatin was taken.

The six subjects included four medical students between 23 and 25 years of age, one mechanic aged 45 and one instructor aged 28 years. All the subjects were in excellent health with normal blood pressures. All work was done with an 800 Gm. load, a 6 cm. stroke and a rate of one contraction per second.

In March 1939, when the experiments began, the circulated (left) muscles were capable of only 300 to 900 Kg. cm. of work. After five weeks of training this ability was doubled or trebled and was still increasing rapidly. Each subject then took 60 Gm. of granular unflavored gelatin³ in fruit juice, soda water or plain water (divided into two doses) each day. This was the quantity of gelatin suggested and used by Ray.¹

Each point plotted is the total work in kilogram centimeters done by the extensor digitorum communis muscle on a given day. A, aminoacetic acid 15 Gm. daily; B, gelatin 60 Gm. daily. The points are connected by lines when the work days follow one another immediately. When work was not done on a particular day, no point is plotted and the line is interrupted. When a subject had to be absent more than two days, a portable ergograph was used each day to maintain training but no point was plotted on the graph. Both subjects had trained their muscles by daily work for more than six months before this graph begins. A fixed rate of work was obtained by using a constant load (1,400 Gm. on circulated muscles, 1,100 Gm. on ischemic muscles), a constant stroke of 6 cm., a constant rate of one stroke per second. Thus the essential variable is the time the subject can continue to work.

Two of the medical students were forced to discontinue gelatin within ten days, owing to apparent gastrointestinal intolerance. The complaint was nausea and a sensation of distention. The remaining four subjects continued the regimen for from twenty-one to thirty-one days. All six subjects continued working daily.

During the gelatin period the ability of all six circulated muscles continued to increase markedly. By the end of May, four weeks after all gelatin was stopped, each of the subjects was able to carry the 800 Gm. load for an indefinite period without fatigue (i. e. steady state). The training during the ingestion of gelatin was indistinguishable from that which occurred before the gelatin or after the gelatin was discontinued.

The ischemic (right) muscle in each case reached maximum ability after three or four weeks of daily work. It showed no further change in its ability (from 200 to 600 Kg. cm.) either as a result of daily work or as a result of the ingestion of gelatin.

The conclusions derived from this group of experiments were that:

1. Gelatin had no influence on the ability of human muscle working without blood supply.

2. No improvement in training of the circulated muscles was effected by gelatin. This did not prove that gelatin had no effect, as the muscles might have been training so rapidly that the effect of the gelatin would not have been visible.

3. The omission of gelatin from the daily regimen did not decrease the ability of those muscles which had been receiving it.

The second group of experiments was to determine what effect gelatin would have on the thoroughly trained muscle. Only two subjects (mechanic and instructor) were available continuously for the full year required for thorough training. These continued to work daily, using a load of 1,100 Gm. on both the circulated and the ischemic muscles. By the end of September and October respectively the ability of the circulated muscle had mounted from 800 to 1,100 Kg. cm. in June to 2,000 to 4,000 Kg. cm. or very close to steady state ability. The load was therefore increased again, this time on the circulated muscle alone, to 1,400 Gm. The ischemic muscles continued to work with a load of 1,100 Gm. The accompanying graph shows the entire subsequent course.

As can be noted, the ability of both the circulated and the ischemic muscles remained virtually constant for the first three months. Aminoacetic acid⁴ 15 Gm. a day was then ingested by each subject for thirty days. This amount was used because it approximates the aminoacetic acid present in 60 Gm. of gelatin. As the graph shows, there was no improvement in work ability during or after the ingestion of aminoacetic acid. Also there was no decline in power after the aminoacetic acid was stopped.

After another two months had elapsed the subjects were given gelatin⁵ again at the rate of 60 Gm. a day. After forty-two days on this regimen each subject had taken about 5 pounds of gelatin. The graph shows that neither the circulated nor the ischemic muscles showed any improvement during the ingestion or any decrease of ability after the gelatin was discontinued.

COMMENT

The obvious criticism of these experiments is that experimental work on only two subjects is not often acceptable. It must be remembered, however, that the data from one well trained muscle are more apt to be valid than the data from a dozen incompletely trained ones. Unfortunately, it is difficult to find subjects who are willing to train their muscles by daily work over a period of many months. The total data here presented show that in six trials the ability of the ischemic human muscle was uninfluenced by the ingestion of gelatin. This is probably a measure of the inherent ability of the neuromuscular unit itself irrespective of changes in the circulation. The data show that in six trials no decrease in ability attended the withdrawal of gelatin. Ray reported that the withdrawal was accompanied by a decrease in the summated ability of the many muscles used in operating a bicycle ergometer. The data show conclusively in two thoroughly trained subjects that the ability of the single circulated muscle was not increased by the ingestion of gelatin. This is

4. Glycocoll-Squibb was the aminoacetic acid used in this experiment.

5. Knox's unflavored "sparkling" gelatin was purchased for this purpose from a local distributor.

3. Swift's "Velvetex" gelatin, purchased from the local office of Swift & Co.

probably a measure of the ability of the combined neuromuscular and cardiovascular systems.

Most experiments dealing with voluntary fatigue of human muscles are open to the criticism that psychic changes can affect them. Is it probable that the subjects used were biased and consciously or unconsciously decreased their effort during the ingestion of gelatin? When a subject works as hard as he can, though only with a single muscle, certain changes occur. The blood pressure rises markedly, the face flushes and the jaw sets, and new associated movements occur and spread with the rise of the effort required to keep going. Such signs were always seen in these experiments. On a number of occasions the blood pressure was taken on the free arm during the work bout. An increase of 60 to 80 mm. of mercury systolic pressure was always found toward the end of the work. I have no doubt that each of the subjects made the maximum effort of which he was capable on every work occasion.

What influence do the present data have on the hypothesis that gelatin will postpone the occurrence of fatigue in work involving the whole body of normal persons? It is conceivable, though unlikely, that the ability of a single muscle might be differently affected by a given procedure than the ability of the body as a whole. However, the only objective data supporting the increased work ability in normal persons due to gelatin are those of Ray and his co-workers.¹ These authors trained their subjects for only two to four weeks before starting the gelatin. They found the gelatin effective only in male subjects and reported a decrease in work ability within ten days after the ingestion of gelatin stopped. Hellebrandt, Rork and Brogdon⁶ tested the influence of gelatin on the ability of female subjects by essentially the same method as that used by Ray. The Wisconsin investigators found no increase in the ability of their women subjects but they pointed out that their subjects could easily maintain a work output two or three times the maximum attained by Ray's male subjects; that the curves presented by Ray could be explained by the process of training without any action of gelatin. Ray's subjects were obviously incompletely trained. They were working daily to complete bodily fatigue. It is unlikely that such fatigue is completely overcome in twenty-four hours. Thus two simultaneous processes might be occurring in these subjects, training tending to increase the work ability and accumulating fatigue (overexercising) tending to decrease the work ability. At first the former process might predominate and ability increase. Later, a plateau might occur and later still staleness would predominate and the work ability decrease. If the gelatin was administered early and discontinued as the second process gains dominance, a curve such as Ray's would result. While all this is theoretical it makes even more imperative the statement of the Council on Foods:⁷ "It should be obvious that observations such as those reported [by Ray, Taylor and Johnson] on six men cannot be applied to all men until experimental confirmation is available from other laboratories."

The failure of aminoacetic acid to influence the work ability of the two thoroughly trained subjects suggests that the mechanism which makes aminoacetic acid effective in myasthenia gravis does not operate in normal

subjects. Since the average American dietary of protein is usually quite adequate, there is no reason to suppose that a supplement of the amino acid aminoacetic acid would be required for efficient function in normal persons.

SUMMARY

In two subjects trained for one year, neither aminoacetic acid 15 Gm. a day for thirty days nor Gelatin (Knox) 60 Gm. a day for forty days increased the work ability of the extensor digitorum communis muscles working with or without blood supply.

In four subjects in the midst of their training period the ingestion of gelatin for from twenty to thirty days produced no obvious difference between the rate of training of those taking gelatin and the rate of training of controls without gelatin.

Clinical Notes, Suggestions and New Instruments

AN UNUSUAL CASE OF ROCKY MOUNTAIN SPOTTED FEVER IN SOUTHEASTERN PENNSYLVANIA

MILTON H. COHEN, M.D., YORK, PA.

The fact that the disease entity with the geographic name of Rocky Mountain spotted fever is appearing with greater frequency in the East is not as well known as the many recent reports would indicate. It was only in 1930 that research workers of the Public Health Service discovered that this disease was present in the states of the Atlantic seaboard. Since then many reports have appeared in the literature describing the epidemiology and clinical manifestations as they appear in the East. Rumreich,¹ Richards,² Crutcher,³ Litterer,⁴ Caton,⁵ Montz,⁶ Parker,⁷ Baker,⁸ Pincoffs and Shaw,⁹ Carey and Duncan,¹⁰ Hampton and Eubank,¹¹ Flippen¹² and many other investigators have conclusively shown that the presence of Rocky Mountain spotted fever in the East is on the increase and that the type as seen in the Rocky Mountain region is identical with that seen along the Eastern seaboard. However, when an isolated case does appear it always represents a considerable diagnostic problem, particularly if it is the first to be seen in the community in which it arises. I therefore felt that the report of the following case would be of interest, first as showing the diagnostic difficulties in a community in southeastern Pennsylvania which hitherto had been free from Rocky Mountain spotted fever, and second because of the occurrence of two features that Dyer¹³ considered to be most unusual—the month (December) in which the infection was contracted and a relapse that occurred one month after the symptoms of the original infection had completely subsided.

REPORT OF CASE

F. S., a white man aged 45, admitted to the York Hospital Dec. 9, 1938, complained of severe headache, fever and nausea. Four days before admission the patient awakened with an excruciating frontal headache, aching pains in the back and legs and marked nausea. His family physician was called and found a temperature of 102 F., a pulse rate of 82 and a respiratory rate of 20. The physical examination revealed no gross abnormality. The headache increased in intensity, requiring the use of morphine; the nausea developed into continuous vomiting and he was sent to the hospital with the tentative diagnosis of typhoid or encephalitis.

The past medical history and the family history were of no particular relevance.

The patient was robust. On physical examination he was dull and drowsy and answered questions irrationally. He was very toxic—coated tongue, foul breath, hot skin. The temperature was 104 F., the pulse rate 102, the respiratory rate 26 and the blood pressure 130 systolic, 76 diastolic. The heart and lungs were normal; no masses were palpable in the abdomen and there was no adenopathy. The neurologic survey was negative.

December 9 the hemoglobin content was 13 Gm., red blood cells numbered 4,000,000, white blood cells 5,800 with a differential count: segmented neutrophils 34 per cent, nonsegmented neutrophils 29 per cent, small lymphocytes 25 per cent, large lymphocytes 1 per cent and monocytes 11 per cent. Analysis of the urine was negative for albumin and sugar. There was no microscopic abnormality. The Kahn reaction was negative.

December 10 the Widal test and agglutination tests for undulant fever and tularemia agglutination were negative. The spinal fluid was clear and colorless, with a pressure of 14 mm. No cells were present. Tests for globulin were negative. Sugar was 55 mg. per hundred cubic centimeters. The result of the mastic test was 00000. The Kahn reaction was negative. Blood cultures yielded no growth (ten days' incubation). Examination of the stool was negative for the typhoid-paratyphoid-dysentery and the gram-positive cocci group. Examination of the urine was negative for the typhoid-paratyphoid-dysentery group.

Four days after his admission the diagnosis was still most uncertain. The continuously high temperature (average of 104 F.) and the comparatively slow pulse (average of 102), the prostration, the delirium and the depression suggested typhoid; but all agglutination tests were negative and no organisms were found in the stool or urine. The severe headache, the nausea and vomiting, the moderate rigidity of the muscles of the neck suggested meningitis or encephalitis, but the normal spinal fluid denied that diagnosis. A few days after his arrival in the hospital a hacking cough developed and scattered rales were heard throughout the chest. Two sputum examinations revealed the presence of pneumococcus type VI and many gram-negative bacilli of *Bacillus influenzae* morphology. X-ray examination of the chest showed no areas of consolidation and physical signs of pneumonia were absent. However, at that time the diagnosis of a virulent type of influenza could not be eliminated. Also tularemia, undulant fever and the typhoid group were still under consideration, in spite of repeated negative agglutination studies.

On December 14, five days after his admission and about nine days after the onset, the first clue to the actual diagnosis was noted. A macular, red, pinpoint eruption was observed on the abdomen. By the next day this rash had spread to his legs, arms, back, palms of his hands and soles of his feet. A few lesions were seen on the roof of his mouth. The color at first disappeared on pressure but later did not. Successive crops of macules appeared and the earlier lesions became darker. Small hemorrhagic areas developed particularly around his ankles. With the appearance of the eruption his symptoms became intensified. Fever rose to 105 F. (axillary), stupor was more pronounced, intense photophobia and conjunctivitis appeared and the spleen became tender and palpable. Retention of urine occurred and repeated catheterizations were necessary.

With the appearance of the eruption the diagnosis was confined to typhus fever or Rocky Mountain spotted fever. A specimen of blood was sent to the Pennsylvania department of health laboratories and the agglutination against *Bacillus proteus* X₁₉ was positive in a titer of 1:2,560. Another specimen

confirmed this finding. The positive Weil-Felix reaction confirmed the diagnosis of a rickettsial infection but did not differentiate between typhus fever and Rocky Mountain spotted fever. The clinical picture also was of no help in making this differentiation. According to Caton,⁵ the temperature runs higher and the disease lasts longer in Rocky Mountain spotted fever. In typhus fever the rash appears first on the chest and abdomen, in Rocky Mountain spotted fever first on the ankles and wrists. But these points are of little significance in an isolated sporadic case and of but little aid in making the diagnosis. It was not until several months after the patient had recovered, when I sent a specimen of his serum to Dr. R. E. Dyer of the United States Public Health Service for protection tests, that the final diagnosis was made. Dr. Dyer reported that the completed protection tests in guinea pigs indicated protection against Rocky Mountain spotted fever.

After the eruption had run its course the clinical picture took a turn for the better. His headache lessened, his temperature declined by lysis and his consciousness improved. Throughout the course of the illness the treatment was simply symptomatic, the most important factor being good nursing care. After his temperature was normal for one week he was discharged on December 29, after a stay of twenty-three days in the hospital. On Jan. 25, 1939, following a period of three weeks during which his temperature was normal and he felt perfectly well, his headache returned and a high fever developed. No rash appeared. Headache, fever, chills and malaise continued for two weeks and then left him with no sequelae. He has been well ever since and has continued his usual occupation in very good physical condition.

COMMENTS

This case was most intriguing in many respects. The differential diagnosis of an unknown fever is always an interesting procedure. After the diagnosis had been made, the first of its kind in York County, the question of origin deserves consideration. Repeated questioning gave no history of a known tick bite. About a week before the onset he had been hunting in the woods close to the Maryland state line, but the tick season in that region persists only from May to October and the eight cases reported by Pincoffs and Shaw⁹ occurred only during that interval. Hampton and Eubank¹¹ point out that in the Atlantic states the incidence begins in May, reaches the peak in July, continues though declines definitely in August and drops abruptly in September and October. The occurrence of a case in December is decidedly unusual. The patient's occupation as a railway station agent required him to handle several shipments of undressed furs about a week before the onset of the fever and headache. Sedlacek¹⁴ reported the case of a meat packer who during the course of his work had to pass hides which were hung from the ceiling of a room. On his way home one evening he felt a bite on his neck and removed a tick. He subsequently contracted Rocky Mountain spotted fever. My patient has no recollection of a tick bite or so definite a source, but the possibility of the furs he handled containing the vector may be one explanation for the source of his infection. The relapse occurring about three weeks after the subsidence of all symptoms is rather unusual. For two weeks it seemed that the whole clinical picture had returned with the exception of the eruption and urinary retention. In a rather thorough survey of the literature I could find no other account of such a relapse.

CONCLUSIONS

A case of Rocky Mountain spotted fever which occurred in eastern Pennsylvania is unusual because of its onset in December and because of the occurrence of a relapse three weeks after the subsidence of all symptoms.

The name Rocky Mountain spotted fever is a suggestive misnomer, for that disease is now endemic along the whole Eastern seaboard and is by no means limited to the Rocky Mountain region. In the diagnosis of the problem of the unknown fever this disease should be kept in mind, and the value of the Weil-Felix and protection tests should be emphasized.

CONTRIBUTIONS OF THE WORLD WAR TO THE ADVANCEMENT OF MEDICINE

J. R. DARNALL, M.D.
Lieutenant Colonel, Medical Corps, U. S. Army
WASHINGTON, D. C.

In Flanders' fields the poppies blow
Between the crosses, row on row,
That mark our place; and in the sky
The larks, still bravely singing, fly
Scarce heard amid the guns below.

So wrote Major John McCrae, a medical officer of the Canadian army, at his dressing station during a lull in the hottest phase of the second battle of Ypres in 1915.¹

Little did he dream, as he created this immortal poem, that it would be cherished as the World War's greatest contribution to poetry. Nor did the harassed people of that day realize that the war would contribute substantially to the advancement of medicine. They were more concerned with what medicine could contribute to the war.

More than sixty million men were mobilized in the sixteen belligerent nations during the World War. About twenty million lives were sacrificed as a direct or indirect result of the war. About ten million soldiers and sailors were killed in action or died from wounds or disease. Approximately twenty million were wounded and nearly seven million were listed as missing or prisoners. Excluding the heavy casualties suffered by civilian populations, more than thirty-four million men were killed in action, died of wounds or disease, were wounded or were missing in action.²

With these appalling statistics in mind, it seems incongruous that the holocaust of 1914-1918 could offer any contributions to the advancement of medicine. Nevertheless, out of the throes of this ghastly war came certain vital contributions to human welfare.

Acknowledging the stupendous tragedy of the war, I will attempt to portray some of the benefits that have arisen from the mud and blood of those hectic years. Only such contributions as have furthered the advancement of medicine will be discussed.

The literature from which this essay is compressed is rich with facts concerning the effects of the great struggle on medicine. The war experiences of distinguished medical leaders have brought forth opinions and conclusions that may now be visualized in the mellow light of elapsed years.

War, whatever its faults may be, invariably serves as a stimulus.³ When the institutions, the freedom, the wealth, the health and the very lives of a people are jeopardized by destructive forces from without, the primal instinct of self preservation becomes a spur to endeavor and accomplishment. Medicine, unless overwhelmed by disaster, is bound to advance more rapidly under the stimulus of war.⁴

During the World War, great nations found themselves in danger of annihilation. Despite terrific losses, the will to survive and triumph promoted progress and accomplishment in all fields. This stimulus produced unprecedented efforts on behalf of the wounded soldier, caused an acceleration of medical achievement and resulted in contributions which tended to offset or compensate for the great loss of life and the economic cost of the war. The destruction wrought was, therefore, an impetus to progress—a stimulus to constructive activities.⁵

The potent but intangible stimulus of this colossal war was an important factor in producing definite contributions to the progress of medicine. These contributions will be considered under the following general headings.

1. Medical organization, education and literature.
2. Surgery and its related specialties.
3. Internal medicine and its related specialties.
4. Physical therapy, occupational therapy and roentgenology.
5. Medical advances in combating the ill effects of chemical agents.
6. Preventive medicine, public health and sanitation.
7. Medical supplies and equipment.

MEDICAL ORGANIZATION, EDUCATION AND LITERATURE

During the World War the best medical men of the time were drawn into the maelstrom of kaleidoscopic events. In each of the belligerent countries these men became organized, with a common purpose.

The internist Dr. Harlow Brooks⁶ spoke of the medical men of the United States as follows: "They were the first of the American Army to enter France and Belgium. The Medical Department was the first to be under fire, the first to suffer casualties and the first to receive death at the hands of the enemy."

In all the warring nations young doctors fresh from school, mature general practitioners and specialists in all branches of medical science were regimented to care for the sick and wounded, prevent disease, supervise sanitation and in various other ways assist in the conservation of the fighting strength of more than sixty million mobilized men. Cohesion, cooperation and team work developed on a greater scale than ever before in the history of medicine.

The best of the medical world were among the first to offer their services. Many of them were dumped unceremoniously into the seething cauldron of unclassified medical officer personnel. Like eggs, they were scrambled together. Many sizzled with righteous indignation at what seemed to be military inefficiency and lack of coordination. These splendid professional men were soon trained to understand and tolerate the red tape and apparent inconsistencies of military life. Their progress toward organized efficiency was essentially along the lines of military team cooperation. Group practice, as is known today, was thus encouraged as the result of the exigencies of war. This development of group medical practice, without displacement of the general practitioner, was an important advance in medicine and an outgrowth of the World War.⁷

Experiences in this war demonstrated the desirability of specialization in various branches of medical science

and showed conclusively that the superman of medicine who was presumably well qualified in all fields of medicine was no more than a myth—an unattainable ideal. As a result of lessons taught by the war, civilian medical practice became enriched by the sturdy growth of specialization. Likewise medicomilitary policy swung away from prewar concepts and leaned toward the idea of special training. Keen minds realized that only deterioration could result from any policy which ignored specialization. The day had long since passed when even the most brilliant medical officer could assimilate the requisite knowledge to perform satisfactorily all the duties which might be required of him. Medical knowledge had become too voluminous.⁸ There arose a school of thought in the Medical Department of the Army that medical officers should not all be obliged to devote their careers to learning everything and excelling in nothing. It was recognized that only by specialization could the highest professional ability be attained.

In the United States Army, after the war, Surgeon General Ireland and his advisers were quick to see this and group practice with specialization was encouraged. This policy was in keeping with the postwar trend in civil practice and it increased the professional prestige and efficiency of the Army Medical Corps tremendously.⁹

In many countries the records of physical examinations of World War conscripts comprise a vast reservoir of statistical data which are of value in studying the incidence of various physical defections in different age groups.¹⁰ There has arisen, as a contribution of the war, an added interest in periodic physical examinations, an added interest in raising the standards of medical education and a popular demand for increased facilities for postgraduate medical training.¹¹

World War contacts and problems promoted a better understanding and cooperation between Regular Army, Navy, National Guard and Reserve medical officers in America and bridged, in the space of a few years, the gap of intolerance, jealousy and distrust which had hitherto hindered medicomilitary progress. This friendly cohesion between various medical groups occurred also in other nations and may be considered an important stride in the march of military medicine, a boon to the federal services and a boost to medical science. In the field of military medicine the World War also brought to all nations a realization of the need for medicomilitary preparedness,¹² including personnel procurement and classification, training, medical supply and medical mobilization plans.¹³

It is true that during the war many medical men were diverted from important peacetime research and practice. But others were pulled out of ruts and dragged from the mire of professional stagnation. Through wartime contacts, responsibilities and experiences they envisaged new and greater fields of endeavor. Many acquired a broadness of perspective that could never have developed in the course of a peacetime career.¹⁴

A wealth of medical literature based on experiences of medical men during the World War has accumulated, thanks to those who were not too inarticulate or too reticent to publish facts, impressions and helpful hints gleaned from their service in uniform. This was facilitated by the organization of professional groups such as the Medical Research Committee of the American Red Cross in France.¹⁵ This committee was composed of members of the Red Cross Commission and of the United States Army Medical Corps. It was appointed for the purpose of stimulating research and aiding in the distribution of the medical information acquired by America's allies during the first years of the war.

Chemists, physiologists, bacteriologists, biologists and pathologists were brought into intimate association with practical clinical problems. The clinical and pathologic conference as an educational medium for interchange of professional knowledge became more widespread as a result of the popularity of such conferences during and immediately after the war.

In addition to showing the need for specialization, the war broadened tremendously the point of view of the specialist. This was accomplished by his close association with other branches of medical work under the stress and strain of fulfilling a great common mission.

In addition to numerous fragmentary writings of educational value, the World War has produced in documentary form a comprehensive record of the United States Army Medical Department activities during that period. These fifteen volumes "The Medical Department of the United States Army in the World War," compiled from records in the Surgeon General's Office¹⁶ under the direction of Major General Merritt W. Ireland, is the most complete chronicle of war medical activities in the history of the world. Other countries, to a lesser degree, have preserved documentary details of their medical activities during this great conflict.

A large section of the Army Medical Museum in Washington, D. C., is filled with specimens acquired during and as a result of the war. These specimens of war pathology are of considerable educational value. Their preservation and display are of real worth to the medical world.

The organized development of public health nursing on a more comprehensive scale was hastened by the war. The value of the nursing profession was more widely recognized and popularized. Nursing education and activities expanded to an unprecedented degree.¹⁷

SURGERY AND ITS RELATED SPECIALTIES

Dr. George Crile¹⁸ in 1920 made the following statement concerning the clinical material created by the World War and its effect on surgical advancement: "So vast was the field that in traumatic surgery the concentrated and accumulated experience of this brief period was greater than the experience along the same lines during the past one hundred years. It follows that during those months many new chapters were opened, some were closed and some discarded, while some were completed and their subject matter stands to be passed on to the benefit of civilian practice."

Improved treatment of wounds stands out as one of several important advances in surgery contributed by the World War.¹⁹ Excision of wounds with primary closure was developed. Débridement, followed by disinfectant irrigation with the Carrel-Dakin technic and delayed closure, was originated and proved highly successful. The war taught the importance of immobilization of wounds of the soft tissues, even when no fractures coexisted. It taught that primary suture is the ideal to be carried out when possible; that delayed primary suture or early secondary resuture should be used when primary suture is impracticable.²⁰

One of the valuable lessons of war surgery was that bacteria of almost any variety can be dormant in healed or healing wounds and may, with slight provocation, cause recurring infection.

Much progress was made through trial and error experimentation concerning the disinfectant qualities of dyes and chlorine preparations.²¹ Of the surgical antiseptics developed by the war, Dakin's solution (diluted solution of sodium hypochlorite) is the most notable. Acriflavine, developed by the British, has also proved to be of considerable value, as has dichloramine-T.

Few will dispute the advances made in orthopedics during the war. Improvements in bone and joint surgery, especially in the treatment of infected joints, bone grafting and amputations, were notable.²² Standardization of, and dissemination of, knowledge concerning the skeletal splints and proper management of fracture cases were accomplished. The names of Blake, Osgood, Allison, Keller, Kirk and others will be remembered in this connection.

World War experience with fractures²³ showed that any method which compressed the part and impeded circulation interfered with the defense against infection, which in turn meant delayed healing. This led to the elimination of the coaptation splint and the substitution of immobilization by fixation with traction. The Balkan frame found its place, and other appurtenances furthering the comfort and rehabilitation of the orthopedic patient were devised. The war brought forth improved prosthetic appliances such as artificial limbs, supporting jackets, belts and braces and showed the need for orthopedic shops at hospitals caring for orthopedic patients.

The radical advance in the treatment of septic arthritis, introduced by Wilms, a Belgian surgeon, during the war, demonstrated the value of free drainage and active motion of infected joints. This was a revolutionary procedure which prevented and will continue to prevent thousands of stiff joints.

The high incidence of "trench foot" increased our knowledge of the damaging effects of prolonged exposure of the extremities to dampness, cold, tight leggings and ill fitting footwear.

A World War observation of little significance at the time led in later years to the development of a unique method of attacking the discouraging problem of chronic osteomyelitis. Dr. William Baer, an orthopedic surgeon of Baltimore, was impressed during his service in France with the clinical paradox presented by maggot-

infested wounds.²⁴ He was puzzled when several soldiers who had lain wounded on the battlefield for a number of days with extensive necrotic wounds were brought to his hospital in surprisingly good condition. He found the wounds infested with maggots, but he was amazed to note that the maggots were cleaning up the necrotic flesh and promoting healing of the damaged tissue.

So strongly was Dr. Baer impressed by this observation that he conducted experiments after the war and found that he could hasten healing in many cases of chronic osteomyelitis which had resisted orthodox methods of treatment. His discovery was presented to the world, and now the raising of maggots for therapeutic purposes is a matter of fact. The happy results obtained by this seemingly abhorrent form of treatment have encouraged its use. But its rise to popularity is naturally slow, owing to the aesthetic considerations and the revulsion at deliberately infesting wounds with these repulsive scavengers of dead flesh.

The popular appeal for maggot therapy has not grown rapidly even though its proponents stress the cleanliness of the technic. The little larvae are reared under almost aseptic conditions, washed thoroughly and preserved in a weak solution of mercury bichloride, which does not seem to harm them. Their scavenger services are utilized, of course, only in conjunction with other surgical methods, including thorough débridement of all accessible necrosed or devitalized tissue.

Anesthesia received careful study and rose to a higher plane during the war.²⁵ The value of nitrous oxide became more widely recognized, and this gas was generally accepted as the anesthetic of choice. The usefulness of spinal block anesthesia was proved, and advances were made in the field of local anesthesia.

Collaboration between laboratory and surgical service was intensified and was a factor in the establishment of improved surgical methods.²⁶

Vascular surgery was enriched. Traumatic aneurysms and other injuries to blood vessels are now handled with greater skill as a result of the war. Knowledge of nerve surgery and tendon transplants increased.²⁷

Blood transfusion was simplified, its dangers determined and minimized, and its field of usefulness extended.²⁸ The prime lesson learned was that transfusion should be done early and not delayed until the condition of the patient became critical. A plan was evolved whereby blood could be grouped, withdrawn and kept sterile, so that at any time within two weeks it could be available for transfusion. When heavy battle casualties were anticipated, supplies of blood for transfusion could be prepared in advance and held in readiness.

Advances were made in the early recognition, control and treatment of wound tetanus. Substantial improvements in brain surgery were attained under the leadership of such skilled specialists as Harvey Cushing.

Modern thoracic surgery may be said to have had its birth during the war as a result of intensive efforts to save those who were victims of chest wounds and

those who were stricken with empyema.²⁹ Not only was the subspecialty of thoracic surgery born, but it was fostered and grew with the skilful labors of such men as Yates, Lilienthal, Graham and Keller.³⁰ Patients with chronic chest suppuration, who prior to the war would have forfeited their lives, are now saved by radical thoracoplastic surgery. Furthermore, the war taught much concerning empyema.³¹ It taught the importance of differentiating streptococcic suppuration from other types of empyema. It taught the importance of early closed drainage in acute empyema. The old, generally accepted method of rib resection and open drainage had often led to chronic suppuration, protracted invalidism and death. Closed drainage of acute empyema now cures many cases, thereby obviating the necessity for open drainage and mutilating thoracoplastic procedures.³²

In dealing with abdominal wounds, surgeons learned the value of speed, large incisions to give visibility and accessibility, and accuracy.³³

Skin grafting operations, always delicate and uncertain, taxed the skill of surgeons during the World War to such an extent that improved techniques were developed. Skin grafting may now be attempted with far greater assurance of success than in the days prior to 1914.

In a substantial degree the World War contributed to the advancement of faciomaxillary and plastic surgery, under the leadership of Blair, Hayes, Hutchinson, Powers and others. It was largely due to the great wealth of clinical material, rather than to any revolutionary discoveries, that these advances were made.³⁴

The paraffin treatment of burns, although a comparatively modest contribution, at least deserves mention as a development of the war.

Surgery shares honors with medicine for the clarification of the nature and treatment of traumatic shock. The brilliant work of Cannon, Crile and Porter threw new light on the pathology, prevention and treatment of this grave condition.³⁵

INTERNAL MEDICINE AND ITS RELATED SPECIALTIES

Most of the medical men who responded to the call during the World War were qualified surgeons or appeared eager to demonstrate surgical ability. Internists were scarce, but, as the war emphasized the need for men trained in this field, greater interest was encouraged. This inevitably led to advancement of internal medicine as a specialty.

During the war, attention was directed to the importance of impaired function rather than to anatomic defects. Cognizance was taken of how a heart acted as well as how it sounded.³⁶ This growth in the physiologic concept of disease was prompted by the experience acquired by countless physical examinations of supposedly normal as well as defective men.

The war taught much concerning food deficiency diseases.³⁷ Necessity and the specter of starvation stimulated research, and the minds of interested medical men were focused on the prevention and correction of those diseases. It is only since the war, and largely as a result of it, that the world has become "vitamin minded." Although much of the investigation of vitamins has been exploited by commercial firms and faddists, there has nevertheless been a high degree of scientific accomplishment in this field. Then too the food shortage of the Central Powers was a gigantic, involuntary experiment in undernutrition.³⁸ It demonstrated gruesomely the harmful effects of undernutrition as exemplified by the sharp increase in the tuberculosis rate and mortality. It also showed the beneficial effect of restricted dietaries in lessening the incidence of diabetes mellitus in the underfed countries.

The World War may not justly be held responsible for the pandemic of influenza which swept over the earth in 1917-1918. But it is logical to surmise that more powerful batteries of medical thought and coordinated action were turned on this disease because of the war.³⁹

Lethargic encephalitis appeared and demanded laboratory and clinical investigation which furthered knowledge of this dreaded malady.⁴⁰ Knowledge of the devastation caused by the streptococcus as a cause of pneumonia was acquired during the war.

The importance of measles as a serious disease as well as an epidemiologic problem was impressed on the medical profession.⁴¹ Likewise the comparatively low virulence, occurrence and contagion rate of scarlet fever were a revelation to many physicians.

The World War epidemics of cerebrospinal fever demonstrated that this disease is a septicemia before meningeal involvement becomes manifest.⁴² It was found that the best therapeutic results were obtained when antimeningococcus serum was given both intravenously and intraspinally. The results were shown to be better than when only the intraspinal administration of serum was employed.

Medical men with the world's military forces were organized in such a manner that they had the unusual opportunity of close professional liaison. They enjoyed diverse official and unofficial channels for dissemination of their individual and group experiences. Accumulated knowledge could be sorted, culled, concentrated and promulgated with greater facility throughout the medical world.⁴³

The doctors of that time were privileged to observe how the respiratory diseases created havoc in the crowded cantonments at home and in the concentration camps of the rear areas. They were able to make comparisons and especially noted the relative mildness of the epidemic in the front lines and in the areas where men who were hardened by outdoor work predominated. But they found that it was the outdoor life and lack of

crowding, rather than hardihood of youth, that minimized the spread of the infection in certain regions.⁴⁴

The retention of clinical cases under military control, where their records could be followed and results of various forms of therapy evaluated, afforded a better groundwork for an ultimate victory over the respiratory diseases than was possible in civil communities. It is true that no startling discoveries were made. But much investigative work was undertaken, and the slow advance was accomplished more by a process of elimination than by brilliant discovery.

The stimulus to scientific endeavor, born of this pandemic of influenza and intensified by its prevalence in the armies of the warring nations, resulted in slow but important gains against this and other infectious diseases.⁴⁵

Although influenza has not yet been conquered, the pneumococcic pneumonias have been tamed and classified, and potent therapeutic serums have been developed for a number of the common types.

Laboratory medicine was also called on to prepare an antitoxin against the fatal ravages of gas gangrene.⁴⁶ This was not accomplished until the latter part of the war, too late to be of widespread practical value to the wounded soldiers of that conflict. But this direct contribution of the World War has proved a godsend to thousands of sufferers since 1918 and, throughout the years to come, countless lives will be saved by this achievement of laboratory science. Medical men of eminence and many whose names are unsung aided in the bacteriologic investigation of gas gangrene and the development of an antitoxin.⁴⁷ Bull of Johns Hopkins and Paul De Kruif of the University of Michigan worked in America. Vincent, Strodel, Weinberg and Séguin in Europe were also notable investigators in this field.⁴⁸

"Trench mouth" became a frequent and troublesome affliction of soldiers during the World War. Its prevalence and its influence on the noneffective rate of troops resulted in laboratory studies which revealed its cause and means of prevention.⁴⁹ Further experimental research demonstrated effective drugs which could be used to destroy the Vincent spirochetes and fusiform bacilli. As a consequence there are now satisfactory therapeutic measures for combating Vincent's stomatitis ("trench mouth").

In the realm of cardiovascular diseases, great progress was made particularly in the recognition and spread of knowledge concerning the vague and nebulous functional disorders of the heart.⁵⁰ Vasmotor instability, effort syndrome, soldier's heart and neurocirculatory asthenia became common phrases in the medical wards, at sick call and with medical examining boards during and after the war. Less conspicuously the World War fostered our knowledge of rheumatic heart disease, syphilitic heart disease and bacterial endocarditis.

As the postwar years have unfolded, war veterans suffering degenerative diseases have flowed in increasing

number into government hospitals, affording hitherto unsurpassed opportunities for studying these diseases. The degenerative afflictions of middle life and older age groups most commonly encountered are the arteriosclerotic cardiovascular ailments. Spectacular and deadly in this group of diseases is coronary thrombosis. It is only since the war, and especially in the last decade, that the medical world has become "coronary conscious," following the pioneer work of Herrick in 1916.

The so-called war nephritis, of obscure etiology, led to extensive investigation of its cause and increased our medical knowledge of renal disease.

The work of Dr. Salmon with the war neuroses is notable. Exceptional opportunity arose for the study of neuropsychiatric diseases, particularly the functional nervous disorders.⁵¹ In this group fell the ill named "shell shock" and the ill famed twilight zone of neuropsychiatric diagnosis, in which malingerers, mental and moral defectives, conscientious objectors and unclassified degenerates sought refuge and safety.⁵²

Fever therapy was used for the first time as a therapeutic agent in the treatment of dementia paralytica during the World War. The blood of two malarial "shell shocked" German soldiers was injected into the veins of patients with the disease in an advanced form and produced encouraging results which led to further work along this line.

Minor mental deviations and endocrine disorders were studied more intensively because of the war and the clinical material which it furnished.⁵³ Studies pertaining to all factors which might influence troop strength and morale were encouraged.

Aircraft development was given a tremendous boost by the World War, and with it came advances in medical knowledge which gave sanction to the birth and growth of aviation medicine.⁵⁴

PHYSICAL THERAPY, OCCUPATIONAL THERAPY AND ROENTGENOLOGY

Physical therapy and occupational therapy formerly were looked on with more or less suspicion and disdain. They were rated by many physicians as bastard offspring of legitimate medicine. But they proved themselves entitled to worthier consideration during the crippling years of the war. These frail and undernourished branches of medicine thrived during the rehabilitation era that followed the armistice.⁵⁵ They have established their usefulness, especially as adjuncts to orthopedics and neuropsychiatry, in hospitals throughout the world.

The most important benefit brought forth in roentgenology by the World War was the perfection of a highly satisfactory method of localization of foreign bodies.⁵⁶ This seemingly small contribution has been of great practical value. One cannot estimate the surgical shock that has been prevented or the number of lives saved by this contribution to medical science.

MEDICAL ADVANCES IN COMBATING THE ILL EFFECTS OF CHEMICAL AGENTS

Chemical warfare, brewed in the laboratories of Germany, was voraciously lapped up by the famished dogs of war and belched forth in 1915 to strike terror and spread dismay among the Allies. Little did the horrified world of that day visualize the beneficent possibilities of this terrible weapon.

Contemporary with the development of chemical warfare agents came medical advances which gave protection from lethal gases.⁵⁷ These accomplishments in chemical warfare defense proved of paramount worth in war time. Necessity had once more become the mother of invention.

Perfection of defense against chemical agents has proved of value in civil industry as well as an adjunct in warfare. Investigation of toxic gases and other harmful chemical agents has focused attention on industrial hazards that had previously commanded scant attention.

Aside from benefits to industrial medicine, extensive laboratory investigation indicates that chemical warfare may be more humane than machine gun fire and high explosives.⁵⁸

Headed by Major General H. L. Gilchrist, an able medical officer whose administrative efficiency and experience in chemical warfare admirably fitted him for its chief, the Chemical Warfare Service of the United States Army carried on extensive research following the war. The laboratories of this service have supported the World War casualty records in acclaiming chemical warfare more humane than warfare which inflicts gunshot wounds.⁵⁹ The general public is slow in recognizing this fact, and many will doubtless refute the contention that chemical warfare has contributed to the advancement of medicine.

PREVENTIVE MEDICINE, PUBLIC HEALTH AND SANITATION

The great war, pregnant with strife and upheaval, delivered into the world an era of preventive medicine.

In 1914 it was discovered that botulism might be caused not only by contaminated meats but by infected vegetables which had been improperly canned.⁶⁰ Food shortage encouraged home canning. This directed attention to the potential danger of widespread outbreaks of botulism. The effects which serious outbreaks due to contaminated foodstuffs would have on military morale accelerated research and propagation of knowledge concerning this disease and its prevention.

While it cannot be said that the war contributed directly to the eradication of typhoid, dysentery, tetanus, meningitis or any of the infectious and contagious diseases, one important lesson was driven home. The war demonstrated beyond all doubt the efficacy of typhoid vaccine and tetanus antitoxin as prophylactic agents. It was possible to compare large groups of men who were vaccinated with large groups of men who were not vaccinated. The incidence of typhoid developing in those who had received protective vaccine was negligible and in striking contrast to the high incidence in armies in which such vaccination was not compulsory.⁶¹

Increased knowledge of the dangers of overcrowding and of the importance of isolating cases and segregating contacts exposed to meningitis, influenza and other infectious respiratory diseases was acquired during the war, when the importance of conservation of man power intensified efforts toward disease control. It was this mass demonstration of effective and ineffective control measures, and the spread of general knowledge among the public concerning effective control measures, which contributed to advancement in this field, rather than important new discoveries.⁶²

Standardized methods of controlling and treating venereal diseases were developed in most of the mobilized armies. These methods were later made applicable to the management of such diseases in civil life.⁶³ After the war, standardization of treatment was adopted throughout the world on a far greater scale than was in effect prior to the war. Likewise, measures aimed at control of the social diseases were promulgated. Educational programs to combat venereal infections were first encouraged in a large way during the World War.

The social and sanitary measures adopted for preventing venereal diseases inhibited the spread of these disabling afflictions among our troops. These measures, based not on sentimental or moral ideas but on a practical working plan, enormously increased the strength and efficiency of the American fighting forces.

The army's candid system of venereal disease control, developed during the World War, should be classed as an outstanding contribution to the advancement of preventive medicine.⁶⁴ Civilian populations throughout the world are now approaching the problem in somewhat the same manner. Enlightened public opinion now encourages educational and other practical control measures. To eliminate the fear and shame and vice consciousness which has become attached to the word "syphilis," Paul De Kruif goes so far as to advocate that it become divorced from loathsome thoughts and be made a cozy, fireside word: a word used in spelling bees and crossword puzzles.

Trench fever, a common disease of the World War, is rare today. Its disappearance is due largely to the improved sanitary knowledge which makes it possible to inhibit its development and prevent its spread. Its former importance can be realized when World War archives are consulted and reveal that at one time approximately 60 per cent of all hospital patients of the British Expeditionary Force were suffering from trench fever. One third of all the sickness in the British army during the World War is thought to have been caused by trench fever. Yet today this louse-borne scourge is scarcely heard of—a forgotten disease conquered as a result of the researches of the American Red Cross Trench Fever Commission.

The Report of the Trench Fever Commission of the American Red Cross Research Commission, published in 1917, is a medical classic of great scientific value and a comprehensive treatise of absorbing interest.⁶⁵

The intensive study and conquest of trench fever led to postwar research concerning other rickettsial diseases. This opened up for more careful clinical investigation the wide and thinly explored field of filtrable virus diseases. Subsequent accomplishments in this

field may be attributed in part to the wartime challenge of trench fever and the research prompted by this disease.

The prevalence of malaria and other protozoan diseases became a military problem of importance in Europe as well as in tropical and subtropical theaters of operation. Appreciable advance was made concerning epidemiology of protozoan infections.⁶⁶

As a result of the war and the acute problem facing European countries, unusual interest became centered in child welfare.⁶⁷ This interest was accentuated by realization that many of the numerous physical defects disclosed by military examining boards might have been prevented by intelligent thought on the subject of child conservation in the past. Sharing the problem of child welfare, pediatrics and public health pushed forward toward new heights.

The return of World War doctors to civil life, trained in sanitation, and the good effects of sanitary control impressed on the minds of the soldiers returning to peaceful pursuits were doubtless powerful factors favoring the future of preventive medicine.⁶⁸ The shortcomings of the past, with respect to hygiene, and the needs for the future were emphasized. The war fostered the propagation of general knowledge concerning sanitation and especially concerning the importance of sputum, excreta, flies, lice and other vermin in the spread of disease.⁶⁹

The education of the public in preventive medical measures is clearly exemplified by the campaign of the American Typhus Fever Commission in poverty-stricken, chaotic Serbia in 1919.

The widespread death-dealing epidemics of typhus fever in Serbia, Poland and Russia, conceived in the hellish poverty and filth of the latter months of the war, bore most bitter fruits in 1919 as an aftermath of the great conflict. Even this fearful disease scourge, viewed in the light of a later era, may be looked on as a blessing in disguise, for it inspired the United States government to send scientific aid and practical relief into Serbia and Poland.

When the large, well organized Typhus Fever Commission went into Serbia, it was given dictatorial powers by the Serbian government that it might save the stricken country. Had the people of Serbia been denied this outside aid, the great plague would have decimated their population, and the survivors would have been none the wiser.⁷⁰ Other epidemics would have followed, and superstitions and fatalistic philosophies would have continued to prevail, had not the American Typhus Fever Commission plunged into the fray and carried its magnificent educational program to successful completion. Due credit is given to the Serbian government for its wholehearted assistance, and to the people of Serbia for their cooperation and gratitude.

Under the heading of preventive medicine, it should be mentioned that submarine warfare and its problems focused medical attention on the dangers of subventila-

tion, the hazards of carbon monoxide and caisson disease. This aroused educational programs to prevent such conditions and led to developments in air conditioning.

The transportation of huge expeditionary forces by ship and train necessitated crowded accommodations and brought many sanitary defects sharply to the attention of responsible officers, whose objectives were the correction of sanitary errors when and if possible. The modern rat-proofing of ships, docks, warehouses and other buildings was promulgated by sanitary studies and experience gained largely from the World War.

There can be no doubt that progress in epidemiology was furthered by the war. That portion of Dr. Victor Vaughan's monumental three-volume work "Epidemiology and Public Health," dealing with meningitis, influenza and the respiratory diseases in general, is based largely on experiences of the World War.⁷¹ These notable volumes have received worldwide recognition as an authoritative reference work on epidemiology.⁷²

As a testimonial of the importance of preventive medicine as demonstrated during the World War, at least three great European powers, England, France and Italy, have each placed in their cabinets a minister of health.

MEDICAL SUPPLIES AND EQUIPMENT

The World War brought forth a greater standardization in medical supplies and equipment than had ever existed before. It created a demand for new and improved methods of manufacture, procurement and distribution.⁷³

Colonel (later Brigadier General) C. R. Darnall had some years earlier achieved a contribution to sanitary science the magnitude of which is scarcely yet realized, notably the purification of drinking water by liquid chlorination.⁷⁴ The practical application of his investigations and ingenious invention is now world wide in scope.⁷⁵ When the United States joined the Allies in 1917 he was selected to organize and administer the Division of Finance and Supply of the Medical Department of the Army. Under his judicious management more than \$350,000,000 worth of medical supplies and equipment were purchased and disbursed, with a smooth efficiency in startling contrast to the inadequate and chaotic medical supply administration of previous wars.⁷⁶

Occasional instances wherein American medical supplies and equipment were insufficient or lacking were invariably traced to exigencies of the service beyond the control of the Medical Department, such as delays incident to priority of manufacture or to priority of shipment accorded other war materials.

The splendid accomplishment of the Medical Supply Division not only resulted in a greater standardization of medical material but opened the way for further development and advance of American commercial research and manufacture of chemicals and drugs as well as other medical supplies and equipment. It uncov-

ered the need and established the groundwork for medical industrial mobilization planning.⁷⁷

As an outgrowth of experience gained during the war, a need was seen by the Medical Supply Division for protecting the interests of the government when contracting for the purchase of drugs and other material under the provisions of regulations requiring competitive bidding. Thus there was developed a testing laboratory at the Army Medical Supply Base at Brooklyn, which insures that drugs and other supplies come up to the standards specified in the purchase contracts. This has resulted in higher quality goods and has led to keener competition on the part of manufacturers. Dishonest bidders are more likely to become discouraged, eliminated and fall into disrepute.

World War experience with medical supplies in all the belligerent countries resulted in improvements which are a distinct contribution to the advancement of medicine.

SUMMARY

We are the dead. Short days ago
We lived, felt dawn, saw sunset glow,
Loved and were loved, and now we lie
In Flanders' fields.

Thus laboring under shell fire and in the blood of his dressing station on the Western Front did a Canadian army doctor lay bare his soul. And throughout the war-stricken world thousands on thousands of other weary doctors labored. The full extent of their accomplishments will never be known.

On the preceding pages are enumerated some of the contributions of the World War to the advancement of medicine. These may be briefly summarized as follows:

1. In the field of medical organization, education and literature the war contributed much to the advancement of medicine. The popularization of group medical practice was an immediate result of the war which showed the medical world the desirability of teamwork, specialization and logical division of labor. This has expedited professional work and has elevated the quality and efficiency of the service rendered. The examinations of conscripts focused public attention on both physical and mental unfitness and the medical-sociological problems incident thereto. The medical and military professions learned the value of cooperation in relation to any future mobilization.

2. In surgery and its related specialties, concrete progress was made as a result of the World War. The clinical material furnished by the war casualties gave impetus to improvements in surgical technic, increased surgical knowledge and improved methods of treatment of wounds. Débridement, the Carrel-Dakin technic, improved management of orthopedic cases, traumatic shock, chronic osteomyelitis, empyema, chest surgery, septic arthritis and blood vessel surgery are but a few of the outstanding achievements. The vast experience gained by all belligerent nations concerning traumatic surgery and the standardization of acceptable forms of treatment were important contributions to medicine.

3. In the realm of internal medicine and its related specialties, notable advance was made as a result of the war. Starving nations studied the science of nutrition and food deficiency diseases. Much investigation was stimulated, although slow progress was made, with the respiratory infections. An antitoxic serum for gas

gangrene was discovered. Increased knowledge was acquired concerning cardiology. Neuropsychiatry was spurred to new attainments. The need for better care of the permanent psychoses was emphasized. Trench mouth was conquered. The prevalent and puzzling disorder known as "war edema" resulted in studies which increased our knowledge of renal disease. Treatment of neurosyphilis with malaria inoculation was instituted.

4. Physical therapy and occupational therapy proved their worth and expanded into valuable adjuncts of such specialties as neuropsychiatry and orthopedics. Roentgenology during the World War was enriched by the perfection of a satisfactory method of localization of foreign bodies.

5. Chemical warfare promoted research and accomplishment in overcoming the ill effects of chemical agents. These contributions aided industrial medicine. Studies of the effects of chemical agents furnished valid evidence that chemical warfare is more humane than warfare which inflicts gunshot wounds.

6. Preventive medicine was elevated to a much higher plane of importance than it had previously occupied. The cause of trench fever, which made great inroads on the effective rate of troops in Europe, was discovered and its ravages controlled. The efficacy of typhoid vaccine and tetanus antitoxin was demonstrated on a grand scale. Standardized methods of controlling and treating venereal diseases were developed. The promulgation of general knowledge concerning sanitation was expanded and accelerated.⁷⁸

The great European epidemics of typhus fever, immediate aftermath of the World War, afforded opportunity for educational campaigns which did much to further the advancement of medicine not only in the stricken countries but throughout the world.

Advances in air conditioning and the propagation of knowledge concerning the dangers of carbon monoxide, subventilation and caisson disease resulted from problems raised by submarine warfare and from the manufacture and employment of munitions. Likewise, sanitary problems of the war stimulated improvements in sanitary devices and brought about the rat-proofing of ships, docks and warehouses. Maintenance of health during the war acquired a new, practical value, which called attention of intelligent people to the fact that it could also be of practical value in peace.

In general, a broad extension of clinical activities in the field of public health was brought about as a result of World War experience. The extraordinary advances in preventive medicine between the Spanish-American and the World War had practical application during the latter conflict. The value of these earlier accomplishments in the field of sanitation was clearly demonstrated between 1914 and 1918. Comparisons between armies which made full use of these earlier advances in preventive medicine and armies which failed to do so could be studied. The contrast was striking. Further progress in laboratory research and in the application of preventive medicine was thus encouraged. Investigators renewed their studies with enthusiasm, and knowledge became more widespread. The importance of sanitation and preventive medicine became more generally recognized.

7. Substantial improvements in the standardization, manufacture and distribution of drugs and other medical

77. Ashburn, P. M.: *A History of the Medical Department of the United States Army*, Boston, Houghton-Mifflin Company, 1929, pp. 308-309.

78. Downes, R. M.: *What Medicine Owes to War and What War Owes to Medicine*, J. Roy. Army M. Corps 67: 381 (Dec.) 1936.

supplies resulted from the World War. When shortage was threatened because of the war there was a stimulus to enter this manufacturing field. American commercial research and manufacture of chemicals, drugs and other medical supplies was encouraged. Improvements in quality of supplies was likewise stimulated by the creation of testing laboratories which discouraged dishonest bidders and purveyors of inferior goods.

CONCLUSIONS

That some good may come from all evil is no better illustrated than by the benefits to humanity that have arisen from the ashes of the World War.

The richest contributions of this great conflict to the advancement of medicine have not been new or revolutionary discoveries but standardization of procedure and equipment together with dissemination of knowledge based on war experience. As the years unfold, the light of knowledge increases and reveals more clearly how medicine has advanced through the storm and blood of the World War.

Many of the discernible and less abstract contributions have been enumerated and discussed in the foregoing pages. In addition to its concrete and tangible achievements, the World War contributed to the advancement of medicine by instilling into the profession a higher sense of duty and idealism, a stronger moral fiber and a deeper pride of constructive accomplishment.

Lieutenant William Fitzsimons, a young army medical officer, was the first American soldier killed in France after the United States entered the war. More than three thousand British medical officers made the supreme sacrifice, while more than twenty-three thousand British physicians were wounded in action. The staggering toll of medical officers of other nations who became casualties in the World War is mute tribute to their patriotism, fearlessness and unselfish devotion to the amelioration of human suffering. They were classed as "noncombatants," yet they displayed a courage and self sacrifice no less than that of their combatant brothers of the line, to whom they rendered such invaluable service.

What contributions of the World War are more constructive, more enduring and more of a boon to posterity than the contributions of wartime physicians to the advancement of medicine? Their loyal and efficient labors engendered an added esteem, prestige and respect for medicine.

We are forced to the conclusion that, as advances were made in the destructive mechanism of war, so also protective and constructive forces struggled for supremacy. Many of the beneficent achievements counterbalanced or outweighed the accomplishments of destructive agents. Many of these admirable contributions might never have come to light except through the darkness and despair of war.

When the medical men and women of the World War come to their journey's end, may their good work be carried on. And may this challenge of a Canadian Army surgeon live to inspire the countless millions yet unborn:

Take up our quarrel with the foe,
To you from failing hands we throw
The torch—be yours to hold it high.
If you break faith with us who die,
We shall not sleep, though poppies grow
In Flanders' fields.

Battle scarred, but enriched by its World War achievements, Medicine marches on.

Council on Pharmacy and Chemistry and Council on Physical Therapy

COUNCILS' COMMITTEE ON CONTRACEPTIVES

THE FOLLOWING WAS PREPARED FOR THE COUNCILS' COMMITTEE ON CONTRACEPTIVES BY GILBERT W. BEEBE AND CLARENCE J. GAMBLE, M.D. IN AUTHORIZING PUBLICATION OF THE REPORT THE COMMITTEE EXPRESSES ITS APPRECIATION TO THE AUTHORS OF THE PAPER FOR THEIR COOPERATIVE AID.

PAUL NICHOLAS LEECH, Secretary
COUNCIL ON PHARMACY AND CHEMISTRY.

HOWARD A. CARTER, Secretary
COUNCIL ON PHYSICAL THERAPY.

CLINICAL CONTRACEPTIVE RESULTS IN A SMALL SERIES OF PATIENTS

GILBERT W. BEEBE

NEW YORK

AND

CLARENCE J. GAMBLE, M.D.

MILTON, MASS.

In 1933 a metropolitan general hospital inaugurated a limited contraceptive service for obstetric patients. The department was not equipped to provide methods requiring individual fitting and believed that a simpler method might have wider acceptance than diaphragm and jelly and thus facilitate child spacing for a larger proportion of patients. Of the simple methods then available, jelly used alone seemed the most promising. A lactic acid jelly¹ was selected on the basis of apparently satisfactory clinical use elsewhere. This was offered to patients at cost, 20 cents for a tube of jelly and 10 cents for an applicator. In order that they might know of alternative and supplementary methods which might provide greater protection than jelly alone the patients were also given information on the greater effectiveness of condom plus jelly, on the low risk days of the menstrual cycle and on the location of an extra-mural clinic where a diaphragm might be fitted.

Two efforts at follow-up have been made in order to study the fertility of the patients thus advised. Both of these have been reported elsewhere;² the present paper being a summary of the second report, which gives in greater detail both the procedure and the results.

THE PATIENTS

The selection of the sample of 197 patients was such that all were white, of demonstrated fertility and possessed of sufficient interest in the control of their reproduction to purchase the supplies offered. The occupational distribution of the husbands, only 5 per cent of whom were unemployed at the second survey period, December 1936 to February 1937, shows that 14 per cent were clerical or white collar workers, 43 per cent skilled laborers or foremen, 40 per cent semi-skilled or unskilled laborers, and 3 per cent of unspeci-

From the National Committee on Maternal Health, Inc., 2 East One Hundred and Third Street, New York.

1. Lactikol B. The authors do not wish to imply that Lactikol B is the only preparation which would be expected to yield results commensurate with those reported here. The present active ingredients given by the manufacturer are 2 per cent lactic acid, 0.05 per cent oxyquinoline sulfate, 16 per cent glycerin, blended carbohydrate gum base. An initial pH of 3.1 and the presence of gum karaya and gum tragacanth have been reported by Leo Shedlovsky, Ph.D. (The Composition of Some Commercial Contraceptive Jellies, *J. Contraception* 4: 179-188 [Oct.] 1939.)
2. Gamble, C. J., and Beebe, G. W.: The Clinical Effectiveness of Lactic Acid Jelly as a Contraceptive. *Am. J. M. Sc.* 104: 79-84 (July) 1937. Beebe, G. W., and Gamble, C. J.: The Effect of Contraception on Human Fertility, *Human Biology* 10: 372-387 (Sept.) 1938.

ceptive practice. It has been shown that before admission:

1. There were the expected religious and occupational differences in the extent of contraceptive practice.

2. While contraception was practiced the risk of conception was almost 60 per cent below that incurred without contraception.

3. Withdrawal, douche or condom, used alone or in combination, was relied on in 90 per cent of the contraceptive practice.

4. The risk of conception while the condom was used alone was 80 per cent below the noncontraceptive level, the corresponding figure for the douche being 40 per cent.

After the hospital had given advice to this interested group:

1. The relative dependence on contraception increased from 65 to 95 per cent.

2. The pregnancy rate for contraceptive practice declined about 70 per cent below the preclinic level, all methods contributing to the increase in protection; the contraceptive rate was about 85 per cent lower than the preclinic noncontraceptive rate of this group.

3. Only 65 per cent of those who purchased the supplies ever used them, and of these 25 per cent were continuing their use 20 months later.

4. It seemed that the technic of instruction, in suggesting alternatives, and the relative inaccessibility of supplies for some had combined to discourage the use of the method advised.

Council on Pharmacy and Chemistry

PRELIMINARY REPORT OF THE COUNCIL

THE COUNCIL HAS AUTHORIZED PUBLICATION OF THE FOLLOWING PRELIMINARY REPORT.

PAUL NICHOLAS LEECH, Secretary.

THE PRESENT STATUS OF LIPOCAIC

Lipoaic is the name which has been suggested by Dragstedt and his co-workers for a new pancreatic hormone concerned in some way with the normal transport and utilization of fat, evidence for which was reported by these investigators in 1936. The authors presented evidence¹ to show that the fatty degeneration and infiltration of the liver which occur in depancreatized dogs treated with insulin is not due to the absence of pancreatic juice (enzymes) or to the small amounts of choline and lecithin present in raw pancreas. They concluded that the beneficial effect of the latter was probably due to some specific substance. They obtained such a substance in alcoholic extracts of beef pancreas, for which was suggested the name Lipoaic.² The method of preparation of the extract was described in detail in a subsequent report.³ About the same time Dragstedt and his co-workers⁴ reported the development of typical atheromatosis and arteriosclerosis in six depancreatized dogs which were maintained for from six to nine months on insulin but which were repeatedly permitted to develop fatty livers of lipoaic deficiency.

Dragstedt⁵ has reviewed the results of these investigations and indicates that the evidence seems sufficient to warrant the

5. Dragstedt, L. R.: The Present Status of Lipoaic, *J. A. M. A.* **114**: 29 (Jan. 6) 1940.

conclusion that the active substance in the pancreas is probably not choline and, since it is not present in the external secretion of the gland, that it represents a specific internal secretion or hormone distinct from insulin. He states that, while the function of the hormone is still but little understood, the known experimental facts indicate that removal of the pancreas in dogs produces in addition to hyperglycemia a lipemia, acidosis and marked accumulation of fat in the liver within two or three days, which can be attributed to a lack of insulin; whereas, with the administration of food, active pancreatic juice (enzymes) and sufficient insulin, early lipemia, acidosis and accumulation of fat in the liver disappear, but later there appears decreased tolerance to insulin and a reduction in the concentration of blood lipids as evidence of the fatty liver of lipoaic deficiency. In 154 depancreatized insulin-maintained dogs examined post mortem the late fatty enlargement of the liver failed to develop in only thirteen animals. If an extract the equivalent of from 60 to 100 mg. of dried pancreas is administered daily either orally or subcutaneously to such an animal when insulin tolerance (dextrose excretion) is minimal, the blood lipids rise to normal and fat disappears from the liver, as demonstrated by biopsy. The author points out that four cases of the latter form of hepatomegaly in human beings with diabetes mellitus well controlled by diet and insulin are reported to have been successfully treated with lipoaic. He suggests that the high incidence of presenile arteriosclerosis as a complication in diabetes, believed by some to be increased with high fat diets, may be related to lipoaic deficiency on the basis of the evidence that arteriosclerosis is produced in depancreatized dogs maintained with such deficiency.

Wolfe⁶ treated 100 cases of diabetic and nondiabetic atherosclerotic gangrene with from 1 to 3 cc. daily or alternate daily injections of a pancreatic tissue extract (Desympatone, Sharp & Dohme, Inc.) in conjunction with other therapy and obtained about 75 per cent healing in all cases. The author attributes the failure of the usual diabetic management in many cases of gangrene to the lack in insulin of some substance present in the pancreatic extract. He concludes that pancreatic extract (enzyme free) in diabetic and arteriosclerotic gangrene seems not only to produce early arrest of pathologic processes but also to stimulate repair more rapidly and completely than any other conservative method. He indicates that the active substance of enzyme-free pancreatic extract exerts beneficial influence on lipid metabolism in general and suggests that the combination of insulin, diet and pancreatic extract may prevent the early appearance of atherosclerosis in diabetes.

Reports of other groups of investigators on the effects of pancreatic extracts have appeared in the foreign as well as the American literature. Neither Wolfe nor Dragstedt has made reference to each other's reports, despite the fact that both investigators published reports concerning pancreatic extracts several years ago. The recent article published by Dragstedt⁵ resulted in an interesting exchange of published correspondence.⁷ The first communication from Barney Lihn, M.D., Vineland, N. J., criticizes the Dragstedt article for failure to refer to the work of the Wolfe group at Temple University. A second communication from Dragstedt suggests that the Wolfe extract is probably not the same as lipoaic. The third and last correspondent, Asher Yaguda, M.D., Newark, N. J., indicates that Wolfe and his colleagues presented an exhibit before the 1937 meeting of the New Jersey State Medical Society at which they are stated to have shown that, in addition to an epinephrine-neutralizing substance, the pancreas also contains a fat-influencing hormone which they called "lipolysin." They are said to have reported a series of cases showing beneficial effects obtained by the use of these two fractions in combination with insulin in patients suffering with diabetes and atheromatosis. Dr. Yaguda states that he asked Wolfe to prepare a summary, which was published in the *Journal of the New Jersey State Medical Society* in March 1938. Reference to this journal reveals a summary report by Wolfe and Digilio⁸ in which no

mention of the fat-influencing hormone is noted. It is simply indicated that pancreatic extract is a promising remedy for the relief of angina pectoris, intermittent claudication, obliterative vascular disease of the extremities and associated symptoms in patients suffering from arteriosclerosis. Whatever evidence may have been presented at the exhibit mentioned, it is not included in the published summary. The report did, however, suggest the *modus operandi* of the substance to be that of a parasympathetic stimulant, to influence fat metabolism and to improve muscle metabolism. The term "lipolysin" was not mentioned.

Following the publication of the correspondents' controversial comments concerning pancreatic extracts, the Council office received the following communication from Dr. J. B. Wolfe of Temple University, Feb. 28, 1940:

As a result of work on various fractions obtained from the pancreas we believe that some of our findings may prove of interest to the members of the section of pharmacology. I am particularly referring to Desympatone (epinephrine influencing fraction) and Lipolysin (fat influencing fraction). Dr. Dragstedt of Chicago worked with a preparation which, we believe, is very similar to ours and obtained some very interesting results. We are writing to you at this time because of some comment in the February 17 issue of *THE JOURNAL* under Correspondence, page 601.

In an effort to obtain some understanding of the difference or similarity between lipocaic (Dragstedt) and lipolysin (Wolfe), the Council office replied by asking Dr. Wolfe to supply a definition of the latter term as used by him. Dr. Wolfe replied March 11, 1940, partly as follows:

We use the term *Lipolysin* as one would interpret broadly the combined word of "splitting-fat." A much better term would be one which would suggest influencing fat, rather than splitting; but when we first used the fraction of the pancreas we were impressed with the following two effects and therefore used the term *lipolysin*:

1. Reduction of cholesterol and phospholipins in the blood.
2. The appearance of a choline or choline-like substance in the urine which gave a positive reaction with Kraut's reagent and after isolation has most of the properties of choline with one exception, and that is that it produces heart block in atropinized animals, while all the other choline preparations such as acetylcholine and mecholyl are pharmacologically inactive following atropinization in certain amounts.

It is quite possible that further researches may prove this term unsuitable.

A further communication from Dr. Wolfe points out that the evidence to suggest the existence of a pancreatic fat-influencing hormone, which is not given in the published summary of his work just noted, was presented on charts at the exhibit mentioned, which explains the conclusion presented in the published summary concerning a possible influence on fat metabolism. According to Dr. Wolfe, these charts included the term "lipolysin" and illustrated the lowering effects of pancreatic extract on phospholipins and cholesterol in patients with angina pectoris and obliterative vascular disease of the extremities. In his communication Dr. Wolfe also calls attention to published summaries⁹ of an earlier report made before the fifteenth International Physiological Congress, August 1935, at which time, he states, were shown illustrations indicating the epinephrine-neutralizing and lipid-lowering effects of pancreatic extract. These illustrations accompany his communication, one of which shows the lowering effects of the extract on whole blood lecithin and serum cholesterol in rabbits. The published summaries, however, do not include this evidence or mention the term "lipolysin"; they mention simply that particular attention was called to a "desympatone" epinephrine-neutralizing fraction and that the work suggested the presence of a lecithin-influencing fraction in insulin-free pancreatic extract. Dr. Wolfe further indicates that, while their methods of standardization of the "desympatone" fraction are fairly satisfactory, the "lipolytic" fraction is as yet difficult to standardize and that because of this difficulty they were not only unable to evaluate their own results with this fraction but could not compare results with those reported by Dragstedt and his co-workers.

Reference to the previous reports of Wolfe and his collaborators indicates that their work was primarily concerned with evidence for the vasodilator and epinephrine-neutralizing properties

of a pancreatic tissue extract furnished by Sharp and Dohme, Inc., under the proprietary name "Desymptone" and its use in the treatment of "angiospastic symptoms," particularly angina pectoris and intermittent claudication. These reports cite references to the similar work of earlier investigators and to reports indicating that extracts of several other tissues exhibit similar properties. The firm of Sharp and Dohme, Inc., now markets what is claimed to be a more highly purified pancreatic extract, free of the reaction-producing constituents of other tissue extracts, for the treatment of intermittent claudication and for ureteral relaxation and dilatation, under a new proprietary name, "Depropanex." The promotion of a pancreatic tissue extract under the proprietary name "Depropanex" (Desympatone) by Sharp and Dohme, Inc., for use in the treatment of any condition on the basis of such meager evidence is considered unfortunate and is certainly not in the interest of scientific therapeutics.

Whether or not the extract Dragstedt has prepared also possesses the vasodilator and other properties of Wolfe's pancreatic tissue extract is not indicated in the former's status report.⁵ Goodpasture et al.¹⁰ and Dragstedt et al.¹¹ have reported a method of assay for lipocaic, and Munch¹² a method for bio-assay of Wolfe's pancreatic extract. While the method of extraction is somewhat similar, the methods of assay reported for the two extracts are quite different. Whether or not crude insulin-enzyme-free extract of the pancreas represents more than one hormonal substance or simply one in which impurities possessing vasodilator properties of tissue extracts in general are present is not clear. Wolfe's published reports do not contain evidence to prove that the two fractions or hormones mentioned in his communications have been isolated.

Stewart and others (including Dragstedt¹³) have reported the use of lipocaic in the treatment of psoriasis, which disease has been felt to involve some degree of metabolic disturbance. An abstract of a later report by Clark, Walsh, Julian and Dragstedt¹⁴ on the same subject, at the meeting of the Federated Biological Societies at New Orleans, indicates that, of the total of twelve cases of psoriasis treated daily with orally administered pancreatic extract, 50 per cent showed almost complete disappearance of the lesions with lipocaic alone and 25 per cent improved more rapidly than usual when local treatment was supplemented by lipocaic, while 25 per cent failed to show any improvement. In the series treated only 50 per cent had an initial hyperlipemia, and, whereas lipocaic tended to lower the blood lipids in all the cases, those with the highest blood lipids seemed to be the most resistant to treatment. The authors indicate that lipocaic seems to be a valuable adjunct in the treatment of psoriasis. While pointing to the favorable effect of lipocaic in psoriasis, the report can hardly be considered as conclusive evidence of its value in this disease. It is noted that Dragstedt did not include reference to this study in his status report.⁵

At present no commercial preparation of lipocaic is marketed. Further investigation to establish the exact nature and physiologic significance of so-called lipocaic appears to be necessary before its place in the treatment of disease can be accurately evaluated. Whether or not it may prove to be another important factor in the treatment of diabetes mellitus is at present only speculative. The results of future investigations are awaited with great interest. In the meantime the use of pancreatic extracts containing lipocaic must be considered as entirely in the experimental stage.

In view of the experimental status of Lipocaic, the Council postponed consideration to await development of further critical evidence and expressed the view that the preparation should not be recognized for routine practice.

SATURDAY, OCTOBER 26, 1940

CASE POSTPONED INDEFINITELY

According to an announcement issued in Washington on October 17 by United States Attorney Edward M. Curran, Justice James W. Morris, who is presiding in Criminal Court No. 2 of the District Court, disqualified himself from sitting on the case because of his former connection with the Justice Department as assistant attorney general. Justice F. Dickinson Letts, now presiding in Court No. 1, is in the middle of a first degree murder case and has a heavy assignment for the next few weeks. "Since no third criminal court is available at the present time," said United States Attorney Edward M. Curran, "I have taken the case off the assignment and it will be set down for trial in the future on a date agreeable to both the government and the defense."

This postponement will release the officials of the Association, therefore, to a continuation of their work in the headquarters office and in other capacities so essential at the present time.

THE PLATFORM OF THE AMERICAN MEDICAL ASSOCIATION

The American Medical Association advocates:

1. The establishment of an agency of the federal government under which shall be coordinated and administered all medical and health functions of the federal government exclusive of those of the Army and Navy.
2. The allotment of such funds as the Congress may make available to any state in actual need, for the prevention of disease, the promotion of health and the care of the sick on proof of such need.
3. The principle that the care of the public health and the provision of medical service to the sick is primarily a local responsibility.
4. The development of a mechanism for meeting the needs of expansion of preventive medical services with local determination of needs and local control of administration.
5. The extension of medical care for the indigent and the medically indigent with local determination of needs and local control of administration.
6. In the extension of medical services to all the people, the utmost utilization of qualified medical and hospital facilities already established.
7. The continued development of the private practice of medicine, subject to such changes as may be necessary to maintain the quality of medical services and to increase their availability.
8. Expansion of public health and medical services consistent with the American system of democracy.

BANTI'S DISEASE OR SYNDROME?

In 1883 Banti described a group of cases characterized by primary enlargement of the spleen, a more or less characteristic secondary hypochromic anemia and a chronic course. The disease passed through typical stages characterized in its advanced stage by hemorrhages from the gastrointestinal tract, ascites and terminal liver cirrhosis. The causative factor was an unknown toxin which acted primarily on the spleen and secondarily on the liver. The essential and distinctive pathologic feature of the spleen was "fibro-adénie" in the malpighian bodies, the process having its inception around the penicillate arteries. This concept received its support from Osler, who defined the new disease entity as follows: "An intoxication of unknown nature characterized by great chronicity. There is a preliminary progressive enlargement of the spleen which cannot be correlated with any known cause, anemia of secondary type with leukopenia, a marked tendency to hemorrhage from the lower esophagus, and a terminal state with cirrhosis of the liver."

The idiopathic nature of Banti's disease soon came into question. Numerous observations appeared demonstrating that splenomegaly and secondary anemia were associated with thrombosis of the splenic or the portal vein. Cauchois¹ collected reports of a number of cases, including his own, of splenomegaly and anemia of pylethrombotic origin. He emphatically refuted Banti's concept. Warthin² concluded on the basis of several observations that "every factor of the symptom complex that Osler lays down as the criterion for splenic anemia is also a factor in the complex of portal sclerosis and thrombosis." Eppinger in his classic treatise on hepatolienal diseases devotes a chapter to the relationship between portal congestion and splenomegaly. Klemperer³ reported a case of cavernomatous transformation of the portal vein presenting clinical and pathologic characteristics corresponding in all respects to that of Banti's. Larrabee,⁴ on the basis of a study of forty-seven cases, concluded that in the majority of cases presenting the clinical picture of Banti's disease the condition is dependent on some intra-abdominal lesion obstructing the venous outflow of the spleen. The commonest of these was liver cirrhosis. He states that "we are forced to the conclusion that most if not all of these cases were not only associated with lesions interfering with the outflow of blood from the spleen but were actually the results of such lesions." Larrabee suggested that the syndrome be referred to as chronic congestive splenomegaly. Johnston,⁵ in his

5. Johnston, J. M.: The Relation of Changes in the Portal Circulation to Splenomegaly of Banti's type, *Ann. Int. Med.* 4: 772 (Jan.) 1931.

study on the relative size of the hepatic portal radicles in splenic anemia and Banti's disease, concluded "We are dealing here with mechanical alterations of the portal blood flow interfering with the free exit of blood from the spleen."

Interesting contributions have recently come from the Combined Spleen Clinic at the Presbyterian Hospital, New York. Rousselot⁶ calls attention to the fact that the appearance of the portal circulation in the course of a splenectomy for Banti's disease is at once indicative of portal hypertension. This dilated and tortuous collection of veins in the splenic pedicle and the enormously dilated veins of the large collateral circulation in the adhesions surrounding the spleen make the removal of the spleen in these cases a formidable and hazardous procedure. This local vascular condition, Rousselot points out, was present regardless of the nature of the "obstructive factor." Microscopic examination of the removed spleens revealed the essential similarity of the changes in the various cases. Thompson⁷ of the same clinic sums up the experience of the clinic comprising 137 cases observed in the past ten years. Of this group 100 cases had been followed under nearly ideal circumstances for clinical investigation. Splenectomies were done in sixty-eight cases. The cases were those of splenomegaly with anemia, leukopenia and thrombocytopenia, development of increased collateral circulation between the portal and peripheral venous circulation and microscopic changes in the spleen that are characteristic. The result of this study is a refutation of Banti's concept. Thompson states "It is our current concept that Banti's disease or splenic anemia is the result of mechanical obstruction to the flow of blood within the portal system. With high portal pressure and relatively low peripheral pressure a reversal in the direction of normal blood flow can take place. This reversal is aided by the absence of valves in the portal system. A careful study of our clinical material leads to the conclusion that there are no significant differences clinically or hematologically between the congestive splenomegalies resulting from the various obstructive factors."

The histologic characteristics of the removed spleens were the same in all groups. All presented variable degrees of follicular atrophy, of fibrosis of the pulp with dilated venous sinuses, and all had the characteristic perifollicular hemorrhages. The obstructive lesions are either intrahepatic or extrahepatic. The intrahepatic lesion is cirrhosis; indeed, hepatic cirrhosis was the obstructive factor in 68 per cent of the cases. Rousselot and Thompson injected silica particles into the splenic veins of dogs and produced after two years a congestive splenomegaly with extensive collateral circulation. Thompson emphasizes that absence of cirrhosis as the

obstructive agent at the time of splenectomy means that it will not appear subsequently. Thus he says "We have yet to see a patient develop the sequence of events characterized by Banti as the three stages of the syndrome."

Thompson and his associates⁸ have made observations on the splenic vein pressure in fifteen cases in the course of operation by inserting the needle of the venous pressure apparatus into the splenic vein. The relatively great increase in splenic pressure in cases of Banti's syndrome when compared with the venous pressure simultaneously recorded in the arm suggests that portal hypertension is an important factor in the production of the chronic splenomegaly.

The contention of the workers of the Combined Spleen Clinic is that Banti's disease or splenic anemia is a secondary mechanical manifestation of any of a variety of lesions producing chronic splenic vein hypertension. They therefore suggest that the terms Banti's disease and splenic anemia be replaced by congestive splenomegaly, as originally suggested by Larrabee.

The type of liver cirrhosis in prolonged schistosomiasis results in the greatest increase in portal pressure and the largest spleens. The behavior of this parasitic disease is ideal for the production of portal hypertension. Campbell,⁹ on the basis of his extensive experience with schistosomiasis in the Orient, expresses the belief that most of the so-called Banti's disease of the Orient is actually schistosomiasis. He considers it probable that the disease as originally described by Banti might be schistosomiasis because of the proximity of Italy to Egypt, where the "Egyptian splenomegaly" has come to be recognized as schistosomal in origin.

THE CLEVELAND MUSEUM OF HEALTH

Effective presentation of health exhibits has been achieved in only a few places, notably at recent world's fairs. Chicago's Century of Progress, the New York World's Fair and the Golden Gate International Exposition, as well as fairs held at Dallas, San Diego and the Great Lakes Exposition at Cleveland, contained health exhibits of notable attractiveness. At all these fairs, exhibits by the American Medical Association were prominent in the display.

The health museum idea is not an innovation. Quacks have used adaptations of it for centuries. Permanent health exhibits have been established from time to time in connection with several leading general museums. Small exhibits have been held in many localities by numerous health agencies. As long ago as 1920, efforts were made on a small scale to establish a health museum in the Harlem district in New York. The Dresden

6. Rousselot, L. M.: The Role of Congestion (Portal Hypertension) in So-Called Banti's Syndrome, *J. A. M. A.* 107: 1788 (Nov. 28) 1936.

7. Thompson, W. P.: The Pathogenesis of Banti's Disease, *Ann. Int. Med.* 14: 255 (Aug.) 1940.

8. Thompson, W. P.; Caughey, J. L.; Whipple, A. O., and Rousselot, L. M.: Splenic Vein Pressure in Congestive Splenomegaly (Banti's Disease), *J. Clin. Investigation* 16: 571 (July) 1937.

9. Campbell, H. E.: Schistosomiasis and Banti's Disease: An Inquiry into Their Possible Relationship, *Chinese M. J.* 53: 459 (May) 1932.

Museum of Hygiene in Germany and the Wunder des Lebens Exposition in Berlin were extensively developed in the decade between 1925 and 1935. Out of the New York World's Fair will grow a permanent health exhibit known as the American Museum of Health. Out of the Chicago Century of Progress and other sources grew the health exhibits at the Rosenwald Museum of Science and Industry in Chicago.

The principles and purposes of health museums have been endorsed by the American Medical Association through participation in the important world or regional expositions as well as through assistance rendered local exhibitors by the Association's Bureau of Exhibits in state and local fairs and temporary health museums. On June 11 the House of Delegates of the American Medical Association adopted a resolution with reference to the American Museum of Health, which states:

Resolved, That the American Medical Association at its ninety-first annual session, held in New York, approves of this museum, urges its constituent and component societies to support and promote the development of similar museums in other parts of the United States and instructs its Board of Trustees, officers and employees to give all possible support to such museums wherever they may be developed in the United States in conjunction with local medical organizations.

The opening of a Health Museum in Cleveland with support from individuals and from civic bodies, among which the Cleveland Academy of Medicine is a leader, is a development directly in accord with the resolution passed by the House of Delegates. Cleveland has long been known as one of America's progressive cities. The addition of a Museum of Health, the first independent institution of its kind actually to be opened in the United States, to existing educational and cultural facilities in Cleveland is a logical step. In time it may well be emulated by many of the larger cities in the United States. Under medical and civic leadership and the technical direction of a physician experienced in exhibit technic, the institution should be a success and should contribute to the health and welfare of the people of Cleveland.

Physicians from Cleveland, the state of Ohio and elsewhere will participate in the formal opening of the Museum, which is to take place November 11 and 12.

During the past decade permanent health exhibits have been established in several museums over the country, especially the Toledo Museum of Science, the Buffalo Museum of Science and the New York Museum of Science and Industry. The most comprehensive group of health exhibits yet to be shown will be opened to the public this month at the Museum of Science and Industry in Chicago.

That the medical sciences should take their place alongside the other sciences that ease the path of man on this earth is perfectly proper. The visitor, coming as he does with an open and receptive mind, is able to obtain a proper perspective of the place that medicine takes in his life.

Current Comment

GUY'S HOSPITAL REPORTS PRESENTS SIR ARTHUR F. HURST NUMBER

The fourth part of the 1939 volume of *Guy's Hospital Reports* is dedicated to Sir Arthur F. Hurst on the occasion of his retirement from editorship. A steady contributor since 1906, Hurst became editor of the *Reports* in 1921. He had contributed to the *Reports* seventy-eight articles, sixty-four of these during his editorship of the *Reports* from 1921 to 1939. The testimonial number contains a complete list of the articles contributed by him to the *Reports* as well as a list of articles contributed by his associates. Fourteen of the more important papers of Sir Arthur have been selected to be reprinted in this issue. They reflect eloquently the breadth of the clinical and scientific interests of the author. The articles deal with the function and the diseases of the esophagus, stomach and intestine, Addison's anemia, asthma and disorders of the nervous system. The volume is a fitting testimonial to Sir Arthur's wide interests and indefatigable energy.

AUTOMOBILE AND MEDICAL EXPENDITURES IN FAMILY BUDGETS

Recent studies by the United States Bureau of Labor Statistics indicate that the much exploited difficulties in the payment for medical care are due more to the increase of expenditures for other items in the family budget than for medical care itself. The Bureau of Labor Statistics has recently set up a new basis for the index figures on costs and standards of living.¹ This required a detailed analysis of all recent budget studies. This analysis broke down the various items in the budget into such classes as food, clothing, fuel, house furnishings and miscellaneous. In this "miscellaneous" item the greatest change in expenditures was found. The periods compared are 1917-1919 with 1934-1939. Expenditures for food and clothing made up a smaller percentage of the family budget in the later period, while the expenditure under "miscellaneous" increased from 17 per cent of the total budget in 1917-1919 to 26.8 per cent in 1934-1939. The new index will be based on 1935-1939 and, when allowances are made for changes in the value of money and the exclusion of certain items which were previously counted as "savings," the percentage of expenditures for "miscellaneous" in the average budget is raised from 23.7 for 1923-1925 to 26.9 in 1935-1939. When this "miscellaneous" item is analyzed, expenditures for automobiles are found to have been practically negligible from 1917 to 1919, but now "in combination automobile purchases and operation constitute almost one fifth of the new miscellaneous index." At the same time the "weight for medical care is less by one half." During the last twenty years the purchase and care of automobiles seem to have had greater appeal than the desire for additional medical service. No doubt improved health has also lessened somewhat the need for more medical service.

MEDICAL PREPAREDNESS

In this section of The Journal each week will appear official notices by the Committee on Medical Preparedness of the American Medical Association, announcements by the Surgeon Generals of the Army, Navy and Public Health Service, and other governmental agencies dealing with medical preparedness, and such other information and announcements as will be useful to the medical profession.

COOPERATION OF HEALTH AGENCIES WITH ARMY AUTHORITIES

In Mobilization of a National Guard Regiment

TRAVIS P. BURROUGHS, M.D.
and

ALFRED L. FRECHETTE, M.D.
Concord, N. H.

At the time of the induction into federal service of one of New Hampshire's National Guard regiments on September 16 the New Hampshire State Board of Health, cooperating with the New Hampshire Tuberculosis Association, the Adjutant General of the state of New Hampshire and the federal military authorities, carried out field laboratory services in the form of chest x-ray examinations, serologic tests of the blood and urinalyses on a total of 1,552 officers and enlisted men. The work had to be completed in nine working days as the regiment was leaving the state on September 26. It was done without delaying or interfering in any way with the army's regular physical examinations, which were done concurrently by the army surgeons.

The facilities provided by the army consisted of a small building formerly used as a cook shack, equipped with electricity, running water and waste drainage. The New Hampshire Tuberculosis Association furnished personnel to take medical histories and technicians for doing the x-ray work. The x-ray unit was under the personal direction of Dr. Robert B. Kerr, executive secretary and clinician of the New Hampshire Tuberculosis Association. The state board of health set up a urinalysis laboratory on the premises and organized a unit for taking specimens of blood for serologic tests and provided a portable x-ray apparatus. The serologic tests were done in the regular laboratory of the state board of health. The workers from the health agencies were assisted by five privates from the medical detachment who were used to direct the flow of men, wash bottles and keep the premises in order.

The personnel of the regiment first underwent their regular army physical examination. Immediately following his physical examination each man proceeded to the laboratory unit. A latrine was built near the shack and as each man reported he was given a urine specimen bottle and asked to void. He entered the laboratory bottle in hand. A card was filled out with his name and short family, medical and occupational history. Army serial numbers not having been assigned, each card had previously been numbered consecutively. Having the cards machine numbered prevented the possibility of duplication or of skipping a number. The number on the card was placed on the urine specimen, the blood tube and the x-ray film. Each man held his own card. The cards were collected as the men went out by another door.

Urine specimens were tested for specific gravity, albumin and sugar. The nitric acid technic was

employed in testing for albumin. A microscopic examination of the centrifuged sediment was done on every specimen showing albumin, followed by examination of a check specimen. Benedict's solution was used for sugar tests. Specimens giving a positive reaction to the qualitative tests were tested quantitatively, followed by examination of a check specimen.

The blood specimens were examined by the Hinton flocculation test. In each instance of a positive reaction a second specimen was taken. This was tested by the Kahn, Kline, Hinton and Eagle technics.

With these facilities and personnel it was found possible to examine 400 men during a nine hour working day. The men could be roentgenographed at the rate of sixty an hour for one or two hours at a time. Rest periods of twenty minutes had to be provided at these intervals, as the personnel could not keep up such a rate for long periods.

To prevent overheating of the x-ray tube, two¹ tube heads were used. After every thirty to forty films the tube heads were changed, so that while one head was in use the other was cooling. It took about three minutes to change heads. The refrigeration room of the cook shack provided an excellent dark room and two workers were kept busy changing cassettes. Six cassettes were used.

The chest x-ray films were taken with a standard² portable unit at a distance of 36 inches at 15 milliamperes and 80 kilovolt peak. Films were unloaded from the cassettes, repacked in the one-half gross cartons in which they came and sent to three local hospitals for developing. If the developed film suggested cardiovascular disease, the individual was taken to the office of a local roentgenologist for fluoroscopic study and 72 inch films.

Blood from nine men was found positive. All were checked. In each case the second blood specimen was also found positive. A trace of albumin was found in the urine in twenty-six cases and a moderate amount in two cases. In one of these the microscopic examination revealed large numbers of hyaline and granular casts. Ninety-two men showed traces of sugar in the urine. On reexamination eleven still had sugar, the largest amount being 0.8 per cent. The question of emotional glycosuria is brought up. Time did not permit continued study to determine whether the glycosuria persisted.

The chest x-ray films revealed seven cases of parenchymal tuberculosis, all minimal. One film revealed a mediastinal tumor, diagnosed as either Hodgkins' disease or lymphosarcoma. Two cases were recommended for further study. In one, a baker, there was a question of yeast infection at the base of one lung, and the other showed a small area of rarefaction in the hilus. In eight cases the 36 inch films were complemented by fluoroscopic study and 72 inch films. One of these was diagnosed as having widening of the arch of the aorta and another as myocardial weakness and dilatation.

MEDICAL PREPAREDNESS

Jour. A. M. A.
Oct. 26, 1940

The cost of this project to the state board of health and the New Hampshire Tuberculosis Association for the special supplies and personal services and the small amount of additional equipment required was \$1,870.35. To this may be added the less obvious cost of salaries of regular personnel of the health department and tuberculosis association utilized in the project, amounting to \$724, and depreciation in value of the x-ray unit estimated at \$200. The total of \$2,794.35 thus derived have justified this expenditure. We feel that the results Detroit tuberculosis case finding program, Dr. Henry Vaughan³ has estimated that the finding of a case of tuberculosis in the minimal stage of the disease is a saving to the community of a thousand dollars. On that basis alone this project recommends itself as an economical and efficient case finding procedure.

All results were turned over to the army surgeons for their use. We might note that none of the men were discharged because of positive serologic reactions. Treatment was instituted by the army surgeons after evaluation of each case. The men with tuberculosis were discharged to the care of the New Hampshire Tuberculosis Association. With a tour of active military service facing them it was quite important to these men that their cases of minimal tuberculosis be detected and that they be spared the exertions of the coming year. It was equally important to the army that these men should not remain to serve as foci of infection to the men quartered with them.

The work on the regiment of 1,400 men was completed within five days. The laboratory stayed open the remaining four days of the encampment as recruits were being enlisted and all candidates for enlistment were examined. A total of 1,552 men went through the laboratory.

It is planned to continue with this program and to have the New Hampshire State Board of Health and the New Hampshire Tuberculosis Association perform the same service for New Hampshire's other National Guard regiment when it is called into federal service. In times of national emergency, army authorities should not have to provide facilities duplicating those already present in health organizations. Many health departments and nonofficial health agencies have facilities such as laboratories and x-ray equipment which can render a valuable service to the army at the present time. Their facilities should be offered and utilized.

COMMITTEE TO CONSERVE MANPOWER IN THE DEFENSE INDUSTRIES

A National Committee for the Conservation of Manpower in Defense Industries has been organized to execute a new plan of coordinating accident prevention efforts throughout the country. The membership includes safety experts from private industry, executives from the national and local safety councils, labor representatives and state officials. Appointed as special agents of the U. S. Department of Labor, the twenty-four members of the committee are serving entirely on a voluntary basis. The new plan to safeguard the defense manpower of the nation in the emergency of Labor following a recent meeting of various interested groups. It aims to bring to industries operating on government contracts, particularly the smaller indus-

trial units, the experience of the country's largest and best managed industries in accident control. According to *National Safety News*, the plan recognizes the basic necessity of state and local health regulations but emphasizes the need for safety education, training and stimulation extending beyond the scope of laws, rules and codes. The program will be carried out with the assistance of regional representatives and district and local contact men. The contact man assigned will volunteer to assist the management of the industrial plant in organizing a safety program and to make an appraisal of physical hazards and submit information on their management for the duration of the contract and beyond, if desired by the management.

The division of labor standards, U. S. Department of Labor, is acting as the clearing house for all activities in connection with the plan. The technical staff of the division's safety and health section is responsible for the preparation, under the direction of the national committee, of procedures, forms, and promotional, educational and technical material. The safety and health section will keep records of accident experience in the defense industries and report its conclusions to the national committee.

RECOMMENDATIONS OF PHILADELPHIA COUNTY SOCIETY

The board of directors of the Philadelphia County Medical Society, September 18, approved two sets of recommendations dealing with the military establishment in its relation to medical practice. The board suggested that every hospital classify its staff under three categories: (a) those who can be most easily spared for military service, (b) those who can be spared in the event of a military emergency and (c) those who cannot be spared under any circumstances. It was suggested that a committee be appointed by the president of the society, including representatives of the Philadelphia Health Council, the board of health and the council of social agencies, to see that medical needs in each section of the city are fulfilled. It was recommended that fees for medical service be adjusted for families whose income has been reduced by conscription or enlistment of the major wage earner.

To protect physicians who serve in the armed forces, the board presented a plan for arrangements with physicians who take over the practice of those in service. First, it was recommended that the physician leaving his practice send cards to his patients stating who is to be in charge of his practice and register the arrangement with the county medical society. The locum tenens should agree to place all funds collected from patients thus turned over to him in a separate fund, to deduct the amount necessary to cover overhead and divide the remaining funds 50-50, and when the practitioner returns from military service to refer all his patients back to him.

The board urged that all institutional, teaching and industrial appointments held by the practitioner be made available to him without loss of rights, seniority or privileges when he returns from service. Those serving in such positions during the emergency should feel that acceptance of them is purely on a temporary basis, the board pointed out.

The board recommended that, during the period of military service of any member of the society, the portion of the annual dues now retained by the society be remitted.

ORGANIZATION SECTION

HOSPITALIZATION OF NEGRO PATIENTS

A REPORT FROM THE COUNCIL ON MEDICAL EDUCATION AND HOSPITALS

During hearings on the Wagner-George hospital construction bill the problems of the hospitalization of Negroes were discussed by a group of persons experienced in hospital administration, which met at the invitation of the Surgeon General of the United States Public Health Service.

It was generally agreed that added and better hospital facilities were needed by the Negroes of the South. It was further agreed that the interests of the colored race would be best served by making provision for them in institutions designed to serve the entire population rather than by the establishment of separate hospitals caring for Negroes only.

Summary of Reports from 111 Negro Hospitals for the Year 1939

	Number	Beds	Admissions	Average Daily Census
General	88	6,413	105,047	3,990
Nervous and mental....	6	9,884	2,783	9,764
Tuberculosis	13	1,317	1,365	1,005
Maternity	1	50	80	33
Hospital departments of institutions	3	85	881	24
Total	111	17,749	110,156	14,816

In most sections of the country existing hospitals of all types and under all auspices admit patients without regard to race or color. Many of them make no separate record of Negro patients, so that a complete census of those patients has been impossible.

However, in the Annual Census of Hospitals for 1932, in response to a question as to whether the hospital admits Negroes, 3,010 other than Negro hospitals and not including any mental hospitals reported in the affirmative. These included 2,442 general hospitals and 568 special hospitals. No census of Negro patients in these hospitals was possible.

From 111 Negro hospitals—those which are limited to Negroes or have separate buildings for that race—

returns showed a total of 17,749 beds, admitting 110,156 patients. Further figures on the occupancy of Negro hospitals are given in the accompanying table. The Negro general hospitals, numbering eighty-eight, with 6,413 beds, had an average occupancy of 3,990 patients; in other words, the Negro general hospitals had an occupancy rate of 62.2 per cent. In all other general hospitals the average occupancy rate was 69.3 per cent. In the Negro general hospitals there were 16.4 admissions per bed—that is, each bed served 16.4 persons during the year on an average. In all other general hospitals the number of patients admitted was 20.3 per bed. This substantiates, in a general way, what has often been observed in particular instances—that Negroes do not utilize existing Negro hospitals to the same extent that the general population utilizes existing hospitals. Contrast is more striking yet on observation that the rate of occupancy for Negro patients in large Negro hospitals provided by municipalities and non-profit organizations on a charity basis runs as follows:

Homer G. Phillips Hospital, St. Louis, 78.0 per cent occupancy.

Kansas City General Hospital No. 2, 70.8 per cent occupancy.
Freedmens' Hospital, Washington, D. C., 79.5 per cent occupancy.

Negro Hospital, Galveston, Texas, 89.7 per cent occupancy.
Grady Hospital, Atlanta, Ga., 77.7 per cent occupancy.

These hospitals were, of course, included in the eighty-eight Negro general hospitals referred to.

In 1938 a special survey of hospital facilities in the state of Mississippi was reported in *THE JOURNAL* June 3, 1939, page 2317.

Each locality has its own peculiar conditions which are to be understood and met in providing hospital facilities for its population. Careful study and consideration in the interests of the whole population in each community should be the basis of action. Due account should be taken of existing facilities.

WESTERN NEW YORK MEDICAL PLAN, INC.

GEORGE R. CRITCHLOW, M.D.

Medical Director
BUFFALO

The Western New York Medical Plan, Inc., was organized late in 1939 after a two year study of the subject of medical expense indemnity by a committee representing the eight counties of western New York: Alleghany, Cattaraugus, Chautauqua, Erie, Genesee, Niagara, Orleans and Wyoming. On enactment of the Piper-Hampton bill into law, providing for the incorporation of nonprofit voluntary medical expense indemnity plans, the committee applied for and received the first certificate of incorporation under the new law. License to operate was issued in February 1940, the plan was offered to the public March 1, and the first contracts became effective March 15. The plan operates under the supervision of the New York State

Department of Insurance after having received the endorsement of the State Department of Social Welfare.

ORGANIZATION

It is a nonprofit corporation. The board of trustees, elected by the participating physician members, consists of twenty-five members—sixteen physicians and nine laymen—made up as follows:

Six physicians engaged in active private practice in Erie County.

One physician from each of the other seven counties included in the plan.

Three physicians nominated by the Eighth District Branch of the Medical Society of the State of New York.

Four persons, not physicians, residents of Erie County.

Four persons, not physicians, from the other counties in the area.

One person, not a physician, a resident of the area, nominated by the Eighth District Branch of the Medical Society of the State of New York.

There are five standing committees for administration:

1. Executive: Seven members, five of whom must be physicians. This committee manages the corporation under the general control of the board of trustees.

2. Financial: Five members of the board of trustees.

3. Medical Advisory: Eleven members, all physicians, who consider matters referred to them relating to inclusion or exclusion of specific medical and surgical services.

4. Reference and Appeals: Twenty members, all physicians, representing all participating counties, to whom may be referred disputed questions of claims for services.

5. Coding: Five physicians from Erie County, one from each other county, whose duty it is to determine professional qualifications of participating physicians based on statements made in their application for membership. Arbitration boards are provided for, one to be set up in each individual controversy, the conclusions of which are binding on the members involved according to an agreement in their contract.

SUBSCRIBERS' ELIGIBILITY

Any person under 65 years of age who has not had cancer, diabetes, osteomyelitis, chronic nephritis, tuberculosis or coronary thrombosis is eligible for membership. Subscribers reaching the age of 65 may continue membership at the discretion of the corporation. Married women must include their husbands in the contract.

Two types of contract are provided:

1. Medical and Surgical Contract: This provides service for all kinds of medical and surgical conditions, but obstetrics and elective operations are not covered in the first year of the contract.

2. Surgical Contract: The benefits of this contract are limited to surgical cases only plus obstetrics (after first year) and an annual physical examination at the request of the subscriber. There is no limit to total benefits.

There are two classes of members:

1. Those whose annual income is less than a specified amount, as follows: (a) Individuals with \$1,800 or less; (b) man and wife with combined income of \$2,500 or less; (c) subscriber and family, including all unmarried children under 18 years of age, with combined income of \$3,000 or less.

Subscribers in this class receive service without further expense (except for co-insurance provision noted later) up to the limit of benefits under the contract, which are as follows: (a) individual, \$200 of service a year; (b) man and wife, \$300 of service a year; (c) family, \$400 of service a year.

2. Those whose annual income exceeds the amounts that have been noted. For this class of subscribers the contract becomes one of pure indemnity according to a definite schedule of indemnities attached to and made a part of the contract. This class of subscribers is subject to the same limitation of total benefits as is the lower income class, but only on the type 1 contract (medical and surgical). Neither class of subscriber is limited as to total benefits under type 2 contract (surgical).

The subscriber may choose his physician from the list of participating physician members. About 75 per cent of the eligible doctors in the area are members.

Emergency treatment by other than member physicians is paid for, but only one half of the amount that would be paid a participating physician.

Obstetric service is furnished only after the first year of the contract.

The general medical and surgical contract includes house and office calls, hospital calls, consultations, spe-

cialists' fees, operations, anesthesia, x-rays, physical therapy, immunization, and laboratory and pathologic examinations (when not furnished subscriber under a separate hospital service contract).

An individual subscriber must pay the physician one half of the first \$10 for service in any contract year (total \$5) on house and office calls for medical (non-surgical) service. Man and wife and family subscribers must pay half of the first \$20 for service in any contract year (total of \$10). This provision is designed to discourage consulting the doctor for trifling and unnecessary reasons.

MEDICAL SERVICES NOT INCLUDED IN THE PLAN

The medical services not included in the plan are:

1. Cases covered by workmen's compensation insurance.

2. Elective operations during the first year of the contract. These are defined as operations which are not imperative but may be desirable.

3. Services rendered in the treatment of venereal diseases acquired as venereal infections, in the first eleven months of the contract.

4. Any ailment or condition arising from the use of drugs or alcohol.

5. All functional nervous or mental diseases in excess of \$50 expense.

6. Injuries or diseases contracted to which a contributing cause was the subscriber's commission of or attempt to commit a felony, or which occurs while the subscriber in engaged in an illegal occupation.

7. Intentional self-inflicted injuries.

8. Services rendered for a condition known to the subscriber to exist at the time the contract became effective.

9. Congenital defects, except in the newborn on a family contract.

SUBSCRIBERS' DUES

The amounts of subscribers' dues are given in the accompanying table.

Subscribers' Dues

	Monthly	Quarterly	Semiannual	Annual
Medical and Surgical Contract				
Subscriber only, no obstetrics..	\$1.50	\$4.50	\$ 9.00	\$18.00
Man and wife, no obstetrics...	2.25	6.75	13.50	27.00
Family group, with obstetrics..	3.00	9.00	18.00	36.00
Surgical Contract				
Subscriber only, no obstetrics..	0.40	1.20	2.40	4.80
Man and wife, no obstetrics...	1.10	3.30	6.60	13.20
Family group, with obstetrics..	1.70	5.10	10.20	20.40

MEDICAL PARTICIPATION

All duly licensed physicians in the district may become members on written application, by payment of the registration fee and signing a contract. Physicians must give written notice of intention to cancel their membership contract, but such termination of membership will not become effective until thirteen months after date of notification.

Physicians who enrolled before April 1, 1940, paid \$10 as a registration fee, which is returnable as corporation funds are available. All membership fees paid after this date are not to be refunded.

Participating physicians render service regardless of the corporation's ability to pay. All remuneration for their services is on a unit basis. Seventy per cent of the premium income the first year and 75 per cent each year thereafter is set aside for the payment of doctors' bills. Payments are made quarterly, and when the value of the unit is below par for the quarter the balance becomes a contingent liability to be paid as earnings accumulate.

Service is evaluated on the basis of an established fee schedule, most of the items of which are below the pre-

vailing schedule for private patients. Where services are rendered subscribers in the higher income group (class 2) the doctor is paid the amount stated in the contract as indemnity and may charge the subscriber an additional fee by private arrangement. The amount of indemnity due the subscriber under his contract is paid direct to the doctor, and the subscriber agrees in his contract to accept the doctor's receipted bill as satisfaction of the corporation's obligation under his contract.

When a subscriber is treated for emergency illness by a nonparticipating physician, whether within or without the area, the corporation indemnifies the subscriber to the extent of one half the amount it would have paid a participating physician for the same service. The subscriber is obligated to the nonparticipating physician for his entire bill.

EXPERIENCE FOR FIRST SIX MONTHS

The first contracts became effective March 15, 1940, and all were of the complete medical and surgical type. The surgical contract (type 2) is being offered the public on Oct. 1, 1940.

The public's reaction to the plan in this first six months may be termed twofold: First, some prospects complained that the rates were too high. Second, employers objected to the discrimination against men with incomes over the limits set by the plan. They felt that it was bad for industrial relations. The field force found that enrolment was slowed up because in many instances executives and foremen lost interest and failed

to push enrolment when they found that they themselves were excluded because of the income ceiling.

The corporation is trying to meet the first reaction, namely the high cost, by offering another type of contract, the surgical, at considerably lower cost. To meet the second objection, the income limit, the plan will henceforth include those above the income limits set in the original plan. However, for this class of subscriber the contract will be one of straight indemnity rather than service, and a fixed amount of indemnity according to an attached schedule will be paid. When subscribers in this class apply for service under their contract the physician has the privilege of fixing his own fee for the service and may collect from the subscriber that agreed fee less the amount of indemnity payable to the subscriber under the schedule of his contract.

Of claims approved during the first quarter of operation the unit value of remuneration was par. The second quarter ended Oct. 1, 1940, at which time doctor bills will be paid on a unit value of better than 90 per cent. The corporation fully expects greatly increased premium income under the modified plan about to be inaugurated. About 750 doctors are members and something less than 1,000 members are enrolled. About 140 claims have been authorized, over half of which have been medical. Rejections have been few, mostly for preexistent conditions and for elective operations.

The State Insurance Department has recently made its first official examination of the corporation's condition and has reported satisfaction in its observations, considering the unexplored field in which the corporation is operating.

MEDICAL ECONOMIC ABSTRACTS

MICHIGAN MEDICAL SERVICE

After ten years of study and an expenditure of \$30,000 in surveys, the Michigan State Medical Society at a special meeting in January 1939 sponsored the formation and operation of a medical service plan.

On the basis of an enabling act (Michigan Public Act 108 of 1939) the Council of the Michigan State Medical Society proceeded to develop the nonprofit corporate structure of the Michigan Medical Service. This involved the advancement of \$7,800 in organizational expenses plus \$10,000 working capital.

Some of the more important phases of the plan are as follows:

First, membership consists of the members of the house of delegates of the Michigan State Medical Society, which elects a board of directors of thirty-five members, two thirds of whom must be doctors of medicine and the remainder representing various lay groups. No member of the board of directors receives compensation for his services as a director.

Second, district medical advisory boards have been established in each of the councilor districts of the Michigan State Medical Society. Members are selected by the county medical societies on the basis of one board member for each hundred doctors of medicine or major fraction thereof in the county medical society. To these boards are referred all problems involving the rendering of medical services and the approval of payment for services.

Third, the Michigan Medical Service was organized on a statewide basis on the recommendation of the Insurance Department of Michigan. Such statewide administration would result in lower administration costs, uniform subscription rates, and greater financial stability through centralization of reserves.

TWO PLANS OFFERED

Both a Medical Service Plan and a Surgical Benefit Plan are offered. The Medical Service Plan provides the services of physicians in the home, office and hospital. The first \$5 incurred for medical services in any one subscription year must

be paid by the subscriber, and total benefits in one year are limited to \$325 for an individual, \$550 for a husband and wife, and \$875 for a family. This service costs \$2 a month for the individual, \$3.50 for a husband and wife and \$4.50 for the entire family including all children under 19 years of age.

The Surgical Benefit Plan provides the following benefits only while the subscriber is a bed patient in a hospital: surgical, diagnostic x-ray and maternity services after twelve consecutive months in the plan. The monthly rate for these services is 40 cents for an individual, \$1.20 for a husband and wife and \$2 for a family including all children under 19 years of age. These rates are increased somewhat if the proportion of female subscribers in any group exceeds 5 per cent. At least 50 per cent of a group of eligible employees must become subscribers, with a minimum of twenty-five. The Surgical Benefit Plan has no age limit, but an age limit of 65 is fixed for the Medical Service Plan.

ENROLMENT

Since the first subscribers were enrolled in March 1940, membership in Michigan Medical Service has increased to 67,449 participants, as of August 29. The total number of subscribers and the enrolment in each plan is shown in table 1.

A steady increase in enrolment of an average of 1,200 new subscribers each month has been obtained during the summer months. The increasing recognition being given to Michigan Medical Service and the presentation during the fall months, when employees are back from vacations, should make possible a greater monthly enrolment.

Of the forty-six groups of subscribers, including employees of organizations such as the Ford Motor Company, the Michigan State Highway Department, People's Outfitting Company, the Booth Newspapers, the Michigan State Unemployment Compensation Commission, the United Detroit Theaters and the Cavin Lumber Yards, six groups elected the Medical Service Plan and forty the Surgical Benefit Plan.

In several of the groups the subscribers are fairly well distributed throughout the state and doctors in practically every county may have patients who are subscribers.

About one fourth of the subscribers are enrolled under individual certificates, one fourth under husband and wife certificates and one half under family certificates (not including the large enrolment of individual subscribers in the Ford Motor Company group).

SERVICES TO PATIENTS

During the first six months, services were provided for more than 3,000 subscribers, and payments to doctors for these services will be in excess of \$125,000.

A sample study of 1,301 patients who received services under the Surgical Benefit Certificate indicates that 23.8 per cent received services for abdominal surgical procedures (6 per cent for hernias, 15.3 per cent for appendectomies, 1.2 per cent for cholecystectomies, 1.3 per cent for all other abdominal procedures); 25.1 per cent for nose and throat surgical procedures (18.3 per cent for tonsillectomies, 4.7 per cent for submucous resections, 2.1 per cent for all other nose and throat surgical procedures); 29.2 per cent for radiology services (10 per cent for chest x-ray films, 5.5 per cent for gastrointestinal series x-ray films, 13.7 per cent for all other radiology services), and 21.9 per cent for all other surgical procedures.

The foregoing study is for the primary surgical services rendered. Frequently the patient required two or more operations at the same time.

A sample study of 357 patients under the Medical Service Certificate indicates that 70.5 per cent required office or home visits of general examinations (48.7 per cent office visits, 10 per cent home visits, 9.5 per cent general physical examinations and 2.3 per cent all other visits and examinations); 9.5 per cent required eye, ear, nose and throat services (5.04 per cent tonsillectomies, 3.36 per cent refractions, 1.12 per cent all other

TABLE 1.—Enrolment

Month	Medical Plan	Surgical Plan	Total
March.....	1,360	56,758	60,118
April.....	1,341	60,368	61,709
May.....	1,352	61,763	63,135
June.....	1,416	63,646	65,062
July.....	1,594	65,388	66,982
August.....	1,700	65,749	67,449

eye, ear, nose and throat procedures); 8 per cent required radiologic services, and 12 per cent required gynecologic, urologic, pathologic and other services.

PAYMENTS TO DOCTORS

For services during the first six months, a total of 826 doctors have been paid \$92,609.45, or an average payment of \$112.12. In addition, payments estimated to be \$33,000 will be made for services rendered during this six month period as soon as incomplete and late monthly service reports can be approved by the medical advisory board.

At least one out of every eight doctors of medicine in Michigan has been paid, through Michigan Medical Service, for services to subscribers.

The average payment for a patient under the Surgical Benefit Plan has been \$46.18; for a patient under the Medical Service Plan, \$15.15, or an average of \$40.44 per patient. The monthly payment to individual doctors has ranged from a low of \$2 for an office visit to a high of \$762.

TABLE 2.—Statement of Experience from March 1 to July 31, 1940

Earned income	\$150,650.55	100.0%
Medical services:		
Paid	\$87,611.45	
Reserve for pending and unreported services	15,434.44	103,045.89
		68.4%
		\$ 47,604.66
Operating expenses		34,691.55*
		23.0%
Income from operation.....		\$ 12,913.03
Other income		1,396.72†
		8.6%
Net income		\$ 14,309.80

* Includes expenses for the month of February.
† "Other income" was derived from the initial \$5 charges under the Medical Service Plan, from registration fees for nonmember doctors and from interest.

Doctors who have received payments for services are located in sixty-one of the eighty-three counties in Michigan.

In each month, the full schedule of benefits, equivalent to prevailing charges now made by doctors in Michigan for patients in the income group enrolled in Michigan Medical Service, has been paid for all services.

STATEMENT OF FINANCIAL EXPERIENCE

Conclusions relative to the financial experience under Michigan Medical Service must be tentative, as the exact status cannot be given until proper accounting can be made for unreported services. The reserve for pending and unreported services includes an allowance of the average cost for all incompletely reported services not yet paid and for an estimated number of unreported services. The latter estimate is based on a short period of operation and will be subject to correction until it can be computed on a longer period of experience.

As of July 31, 1940, the financial status for the first five months is shown in table 2.

An examination of the experiences under Michigan Medical Service to date indicates that the people in Michigan desire to participate in a nonprofit, nonpolitical, prepayment medical service plan. The inauguration of such a program by the medical profession can further the ideals of a great profession as well as arrange for the payment of medical services on a democratic basis. It appears increasingly evident that the success of the medical service plan will depend on the degree of cooperation it receives from doctors of medicine.

WOMAN'S AUXILIARY

Mississippi

The woman's auxiliary to the Northeast Mississippi Thirteen Counties Medical Society held its second quarterly meeting, June 11, at Macon with the president, Mrs. Bernard Patrick, presiding. The state president, Mrs. E. C. Parker of Gulfport, was guest of honor and presented her plan for the work of the auxiliaries, stressing June as Hygieia month, July as accident prevention month and August as doctors' check-up month. Dr. J. P. Wall, of Jackson, past president of the Mississippi State Medical Association, addressed the auxiliary on "The Menace of Socialized Medicine to the Present High Quality of Medical Service in the United States." Entertainment included tours of Macon's gardens and a barbecue.

Nebraska

The board of directors of the auxiliary to the Nebraska State Medical Association met September 17, Mrs. A. D. Brown, Central City, state president, presiding. At a luncheon given by

Mrs. Brown, the guest of honor was Mrs. V. E. Holcombe of Charleston, W. Va., President of the Auxiliary to the American Medical Association. The members then attended a tea at the home of Mrs. J. Dewey Bisgard, given by the Omaha-Douglas Counties auxiliary.

South Dakota

Mrs. V. Eugene Holcombe of Charleston, W. Va., national president of the Medical Auxiliary, was in Huron, S. D., September 21, to attend a board meeting of the South Dakota State Medical Auxiliary. Those present were Mrs. R. A. Buchanan, Huron, state president; Mrs. F. C. Nilsson, Sioux Falls, president-elect; Mrs. G. H. Gulbrandson, Brookings, first vice president; Mrs. B. M. Hart, Onida, second vice president; Mrs. J. C. Hagin, Miller, recording secretary, and Mrs. J. C. Shirley, Huron, corresponding secretary and treasurer. Also present were committee chairman and district chairmen Mrs. Odah D. Stout, Pierre; Mrs. G. E. Burman, Carthage; Mrs. B. A. Bobb, Mitchell; Mrs. N. K. Hopkins, Arlington; Mrs. M. W. Pangborn, Miller, and Mrs. A. D. Hyden, Sioux Falls.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION AND PUBLIC HEALTH.)

ADDITIONAL MEDICAL COLLEGE NEWS AND ARTICLES APPEAR IN THE STUDENT SECTION, PAGE 1495.

ARIZONA

State Health Officer in Military Service.—Dr. Frederick P. Perkins, Phoenix, recently appointed secretary and state superintendent of public health, left with the 158th Infantry of the Arizona National Guard for training camp at Fort Sill, Okla., September 23, according to *Public Health News*.

ARKANSAS

Changes in Health Officers.—Dr. Gardner H. Landers, Texarkana, has been appointed health director for Independence County. —Dr. Ewing M. Nixon, Little Rock, has been appointed director of the Mississippi County health unit with headquarters at Blytheville. He succeeds Dr. Roy E. Schirmer. —Dr. Ralph E. Weddington, formerly of Fort Smith, has been named medical director of district number seventeen with headquarters at Melbourne.

Society News.—The Sebastian County Medical Society was addressed, September 10, by Drs. Everett C. Moulton on "Hypertensive Retinitis" and Charles H. Finney, Fort Smith, "Hypertensive Cardiovascular Renal Disease." —Dr. Thomas D. Moore discussed "Use and Abuse of Urinary Antiseptics" before the Mississippi County Medical Society in Blytheville, September 3, and Dr. Conley H. Sanford, "Management of the Aged Patient." Both are of Memphis. —Among others, Drs. Joseph F. Shuffield and Paul L. Mahoney, both of Little Rock, addressed the Sevier County Medical Society in DeQueen, September 10, on "Fractures of the Wrist and Ankle" and "Chronic Cough Hemoptysis," respectively. —The Pulaski County Medical Society was addressed, September 16, by Dr. Silas C. Fulmer, Little Rock, on nephritis.

CALIFORNIA

Southern California Meeting.—The Southern California Medical Association will hold its one hundred and third semi-annual meeting at the California Hotel, San Bernardino, November 15-16. The program will consist of two symposiums, one on the present status of hypertension and the other on nonmalignant diseases of the colon, and the following papers:

- Dr. Milo K. Tedstrom, Santa Ana, Postural Hypotension; Report of Two Cases.
- Dr. Thomas Addis, San Francisco, Treatment of Nephritis.
- Dr. Frederick L. Reichert, San Francisco, Circulatory Disturbance in the Upper and Lower Extremities.
- Dr. Louis C. Bennett, Los Angeles, Intubation Management of Distention in Intestinal Obstruction.
- Dr. James Vernon Luck, Los Angeles, Differential Diagnosis in Low Back Pain.
- Dr. Charles Hunter Shelden, San Marino, Surgical Treatment of Spinal Cord Tumors.
- Dr. Norman H. Williams, Beverly Hills, The Puerperal Cervix.

ILLINOIS

Personal.—Dr. Cornelius E. Kline, formerly of Vienna, has been appointed in charge of the Moline district health unit, succeeding Dr. Carl A. Peterson, who resigned on account of ill health.

Changes in State Personnel.—Dr. Roland R. Cross, Dahlgren, assistant director, state department of health, has been named acting health director and Dr. George W. Morrow, managing director of the Kankakee State Hospital, has been named acting director of public welfare, newspapers reported, October 19. The new appointees succeed Dr. Albert C. Baxter and A. L. Bowen, respectively. Dr. Cross graduated at the American Medical College, St. Louis, in 1910 and Dr. Morrow at the College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1908.

Society News.—Dr. Charles M. Wilhelmj, Omaha, discussed "Physiologic Aspects of Shock" before the St. Clair County Medical Society, September 5, in East St. Louis. —The Coles-Cumberland County Medical Society will be addressed, November 20, by Dr. Earl O. Latimer, Chicago, on "Anatomic Considerations in Repair of Inguinal and Femoral Herniae." —Dr. Leo K. Campbell, Chicago, will discuss

"Benefits and Dangers of Reducing" before the Stephenson County Medical Society in Freeport, November 21. Dr. Nathaniel G. Alcock, Iowa City, will address the society, December 19, on "The Value of Urological Findings in the Diagnosis of Abdominal Tumors." —Dr. Horton R. Casparis, Nashville, Tenn., discussed "Importance of Cooperation in Mental Health" before the Peoria City Medical Society, October 8.

CHICAGO

Personal.—Dr. Robert S. Berghoff, clinical professor of medicine, Loyola University School of Medicine, was recently awarded honorary membership in Alpha Omega Alpha at his alma mater, St. Louis University School of Medicine, St. Louis.

New Hematologic Service.—A new hematologic service at the Michael Reese Hospital has been opened under the direction of Dr. Raphael Isaacs. In addition to the treatment of patients and the study of blood, it is planned to carry on research work in diseases of the blood and blood-forming organs.

Dr. Carlson Presents Library to University.—Dr. Anton J. Carlson, professor and chairman of the department of physiology, Division of Biological Sciences, University of Chicago, has presented his scientific library to the university. His collection includes about 16,000 classified reprints of scientific articles, 1,200 books and research monographs, and complete files of fifteen journals. Dr. Carlson, who completed thirty-six years of active service on the university's faculty when he retired October 1, intends to remain active in research work. He will be professor emeritus.

Anniversary of Birth of Christian Fenger.—Northwestern University Medical School will observe the one hundredth anniversary of the birth of Dr. Christian Fenger with a special convocation in the Archibald Church Library, November 4. The centennial address will be delivered by J. Christian Bay, LL.D., librarian of the John Crerar Library of Chicago. There will be a display of numerous publications of Dr. Fenger's, including his thesis on "Carcinoma of the Stomach," which was submitted to the faculty of the University of Copenhagen for the degree of doctor of medicine. A death mask of Dr. Fenger will also be shown. In 1882 Dr. Fenger was appointed professor of pathology at Northwestern and in 1893 he became professor of surgery and chief of the surgical service of Passavant Hospital.

Society News.—The Polish Medical Society of Chicago was addressed, September 26, by Dr. Francis E. Sencar on "Office Dermatology." —Among others, Drs. Abraham A. Low and Elizabeth P. MacDougall addressed the Illinois Psychiatric Society, October 3, on "Combined Picrotoxin and Metrazol Treatment of Mental Patients." —The Chicago Roentgen Society was addressed, October 10, among others, by Drs. Jerry J. Kearns and Harold C. Voris on "The Early Management of Acute Head Injuries." —The Chicago Pediatric Society was addressed, October 15, by Drs. Katsuji Kato and Pei-kuang Li on "Determination of Blood Pyruvic Acid in Infants and Children: An Attempt to Diagnose Subclinical Deficiency of Vitamin B₁." —Bernard Gumbiner, "Spontaneous Pneumomediastinum in the Newborn Infant," and Stanley Gibson, "Auricular Fibrillation in Childhood." —Dr. Cornelius P. Rhoads, New York, will address a joint meeting of the Institute of Medicine of Chicago and the Chicago Society of Internal Medicine, October 28, on "Physiological Aspects of Vitamin Deficiency." —The Society of Medical History of Chicago will be addressed, November 4, by Drs. Abraham Levinson on "Medical Medallions"; James E. Lebensohn, "Wollaston and Hemianopsia," and Jerome R. Head, "Bretonneau, Trousseau and Velpeau."

INDIANA

University News.—Dr. Alexander T. Ross, former research neurologist of the Michigan Farm Colony for Epileptics, now known as the Caro State Hospital for Epileptics, Wahjamega, Mich., has been appointed assistant professor of neurology at Indiana University School of Medicine, Indianapolis. Dr. Joseph E. Tether Jr. has been named as assistant to Dr. John D. Van Nuys, director of admissions of the university hospitals.

Dr. Harvey Resigns.—Dr. Verne K. Harvey has resigned as director of the Indiana State Board of Health, Indianapolis, to become chief medical officer of the U. S. Civil Service Commission at Washington, D. C., newspapers reported, October 1. Dr. Harvey graduated at the Indiana University School of Medicine in 1929. He received a certificate in public health at Johns Hopkins University in 1933, in which year he was named director of health of Indiana. He has been associate in pathology and bacteriology at his alma mater.

KANSAS

Society News.—Dr. Raynar T. Westman discussed "Undulant Fever" before the Wyandotte County Medical Society, Kansas City, September 24, and Dr. Lewis W. Angle, "Treatment of Postoperative Abdominal Wall Ulcers." Both are of Kansas City.—The Golden Belt Medical Society was addressed in Minneapolis, October 3, by Drs. Clyde B. Trees, Topeka, on "Hip Nailing"; George F. Gsell, Wichita, "Evaluation of Ocular Discomfort"; Abraham E. Hiebert, Wichita, "Treatment of Burns," and Morris Polsky, Kansas City, Mo.; dermatology.—A symposium on diabetes mellitus was presented before the Shawnee County Medical Society, Topeka, October 7, by Drs. Don C. Wakeman, Archibald J. Brier, Paul E. Belknap, John L. Lattimore and James D. Bowen, all of Topeka.

LOUISIANA

Personal.—Dr. James Welch, Long Leaf, has been made medical director of the Central Louisiana Hospital for Insane in Pineville. Dr. Arthur L. Seale, who has been in charge of the hospital since Dr. Stonewall J. Phillips resigned as superintendent several months ago, was made assistant medical director.

MAINE

Fall Clinical Session.—The Maine Medical Association held its annual fall clinical session in Bangor, October 17, at the Bangor House and the Eastern Maine General Hospital. The first evening was devoted to a discussion of obstetrics by Dr. Abraham N. Creadick, associate clinical professor of obstetrics and gynecology, Yale University School of Medicine, New Haven, Conn. The second day was devoted to case presentations, clinical observations and symposiums. A lecture by Dr. George C. Wilkins, Manchester, N. H., on "The New Hampshire Plan for Cancer Control" concluded the program.

MARYLAND

Society News.—A dinner meeting of the Maryland Psychiatric Society and the neuropsychiatric section of the Baltimore City Medical Society, October 10, was addressed by Wade H. Marshall, Ph.D., and Philip Bard, Ph.D., on "The Segmental Basis of Cortical Localization" and Dr. Robert V. Seliger, "The Rehabilitation of the Alcoholic." All are from Baltimore.—A symposium on peptic ulcer was presented before the Baltimore City Medical Society, October 4, by Drs. William F. Rienhoff Jr., Lay Martin and Ernest H. Gaither. At a meeting of the society, October 20, the speakers were Drs. Oliver S. Lloyd, "A New Type of Lag Screw for Internal Fixation of Fractures of the Neck of the Femur"; Amos R. Koontz, "Experiences with the Injection Treatment of Hernia," and Harold R. Bohlman, "Sulfanilamide in the Treatment of Gas Gangrene, Compound Fractures and Traumatic Wounds."

MICHIGAN

Hospital News.—A new hospital is under construction at the Pontiac Motor Company, Pontiac. The unit is a single story brick building, containing two, four and six bed rest wards, pharmacy, eye examination room, nurses' rest room, medical records room and a complete operating room for emergency cases. It is air conditioned and will be connected with the Pontiac personnel offices. Dr. Ethan B. Cudney, medical director for the division, will be in charge.

Society News.—Dr. Frank H. Bethell, Ann Arbor, discussed "Anemias Related to Nutritional Deficiencies with Particular Reference to Pregnancy" before the medical section of the Wayne County Medical Society, Detroit, October 14.—The Southern Division of the Wayne County Medical Society was constituted an official branch of the parent organization by action of the council, October 4. Officers include Drs. Robert H. Proud, Flat Rock, president; Maurice P. Miller, Trenton, president-elect; John W. Nagle, Wyandotte, secretary and treasurer, and William H. Honor, Wyandotte, counselor for the ensuing year. The East Side, West Side, Highland Park, Dearborn and Southern medical societies are now within the framework of the county organization.

Symposium on Industrial Health.—The Saginaw County Medical Society will present a symposium on industrial health and safety at the Bancroft Hotel, Saginaw, November 12. Included among the speakers will be:

Dr. Kenneth E. Markuson, Lansing, Function and Services of the Industrial Hygiene Bureau of the Michigan Department of Health.
Melvin First, industrial hygienist, Northeastern district, Industrial Hygiene in the Saginaw Valley.

M. A. Snell, supervising engineer, Hartford Accident & Indemnity Company, Hartford, Conn., The Economy of an Adequate Industrial Health and Safety Program.

C. Grant Watters, Detroit, Industrial Safety and the Preservation of Manpower.

Ralph L. Lee, department of public relations, General Motors Corporation, The Public Relations Value of an Adequate Industrial Health and Safety Program.

Dr. Charles F. Engel, Homestead, Pa., The Industrial Physician and His Relation to Industrial Health and Safety.

Ethel Langenberg, R.N., Detroit, The Nurse in Industry.

C. E. Etheridge, treasurer, Macklin Company, Jackson, The Manufacturer's Evaluation of Industrial Health and Safety.

H. R. Ohlheiser, industrial hygienist, laboratory of industrial hygiene and toxicology, Fidelity and Casualty Company of New York, Industrial Health and Safety and Their Relation to National Defense.

At the dinner meeting, the speakers will be Drs. Frank Novy, Saginaw, and Henry Cook, Flint, president of the county medical society and chairman of the industrial health committee of the state medical society, respectively.

MINNESOTA

Officers of State Board of Health.—Dr. Erling S. Platou, Minneapolis, was recently reelected president of the Minnesota State Board of Health and Dr. Thomas B. Magath, Rochester, was elected vice president succeeding Mr. T. G. Bell, Duluth, who retired from the board. Leo Thompson, Little Falls, has been named to succeed Mr. Bell as a member and Dr. Frederick W. Behmler, Morris, has been appointed to succeed Dr. Edward T. Fitzgerald, Morris. Other members of the board are Dr. Ruth E. Boynton, Minneapolis; F. E. Bass, C.E., Minneapolis; Dr. Albert G. Schulze, St. Paul; A. C. Kean, D.D.S., Grand Rapids, and Gustav Bachman, Pharm.D., Minneapolis. Dr. Albert J. Chesley, St. Paul, was reappointed as secretary and executive officer.

Society News.—Dr. Arnold Schwyzer presented a paper before the Minnesota Academy of Medicine, St. Paul, October 9, entitled "Ulcerative Colitis."—A symposium on diseases of the blood was presented before the Ramsey County Medical Society, St. Paul, September 30. Dr. Ralph W. Warnock discussed "The Anemias" and Dr. Emmett V. Kenefick, "Leukemias and Leukemoid Reactions."—Dr. Irvine McQuarrie, Minneapolis, discussed "The Effect of War on Civilian Health in China" before the Hennepin County Medical Society, October 23. At the meeting October 30 the speakers will be Dr. Robert G. Green on "The Typical Characters of Virus Infections" and Dr. Erling S. Platou and Robert E. Hoyt, M.S., "Human Serum in Streptococcal Infections."—Dr. Henry C. Sweany, Chicago, gave a lecture at the Mayo Clinic, Rochester, October 1, on "Age Criteria in the Pathology of Tuberculosis."

MONTANA

Division of Industrial Hygiene.—A state division of industrial hygiene has been organized at Helena, according to the *Journal-Lancet*. Created by the 1939 legislature, the division will study health conditions and occupational diseases among workers in the state, investigate sanitary conditions and enforce industrial health regulations.

NEBRASKA

Society News.—Drs. Frank P. Murphy and Philip L. Romonek addressed the Omaha-Douglas County Medical Society, Omaha, September 24, on "First Aid to the Newborn" and "Carcinoma of the Larynx" respectively. Drs. Willis H. Taylor and Charles P. Baker presented case reports on intracranial hemorrhage in the newborn and congenital heart disease in the newborn. All are of Omaha.

NEW YORK

Society News.—Dr. Charles Gilmore Kerley, New York, addressed the Dutchess County Medical Society in Poughkeepsie, October 16, on "Thyroid Gland Abnormalities in Infants and Children."—At a meeting of the Medical Society of the County of Westchester, White Plains, October 15, Dr. William P. Thompson, New York, made an address on "An Evaluation of Newer Laboratory Methods."—Speakers at a meeting of the Syracuse Academy of Medicine, October 15, included Dr. Edward C. Hughes on "The Relationship of the Thyroid and Adrenal Glands to the Toxemias of Pregnancy."

New York City

Award to Head of Infantile Paralysis Foundation.—Mr. Basil O'Connor, president of the National Foundation for Infantile Paralysis, received the Goodrich Award for Distinguished Public Service at a ceremony in the B. F. Goodrich Arena at the New York World's Fair, October 15. In accept-

MEDICAL NEWS

1467

ing the award, Mr. O'Connor called it a "recognition by industry of the value of the work of the National Foundation for Infantile Paralysis to the public as a whole."

Appointments at Postgraduate Medical School.—Announcement is made of the appointment of Dr. Henry H. Ritter as executive officer of the department of traumatic surgery at New York Post-Graduate Medical School and Hospital, with the founder of the department, Dr. John J. Moorhead, remaining as consultant. Dr. George Anopol is now executive officer of the department of orthopedic surgery, succeeding Dr. Charles Ogilvy, who remains as consultant. Dr. Irving S. Wright has been made executive officer of the department of medicine, succeeding Dr. Walter G. Lough. Dr. Lough, previously professor of clinical medicine, becomes clinical professor of medicine.

NORTH CAROLINA

Ninth District Meeting.—The annual meeting of the Ninth District Medical Society was held in Mooresville, September 26. Dr. Dickinson Sergeant Pepper, Philadelphia, was the guest speaker at a banquet on "The Use of Sulfapyridine and Sulfathiazole in the Treatment of Pneumonia." Other speakers included Drs. John W. Erwin, Morganton, on "Thrombocytopenia with Leukopenia of Unknown Origin"; Carl V. Reynolds, state health officer, Raleigh, "Why a Health Department?"; James P. Rousseau, Winston-Salem, "Pituitary Adenomas"; Creighton Wrenn, Mooresville, "Some Complications of Pregnancy," and Lieut. Col. John H. Sturgeon, Fort Bragg, "The Physicians' Duties for Mobilization Under the Selective Service Act."

Memorial Hospital Dedicated.—Ceremonies dedicating the new Memorial Hospital were held in Charlotte, October 1, and the building was opened to patients October 7. Governor Clyde Hoey made the dedicatory address. Other speakers were Dr. William H. Walsh, Chicago, hospital consultant; Dr. Malcolm T. MacEachern, director of hospital activities, American College of Surgeons, Chicago, and Mr. C. Russell Shetterly, associate general counsel, Public Works Administration, Washington, D. C. The hospital has 325 beds including bassinets, and affiliated with it is the Good Samaritan Hospital with 100 beds for Negro patients. Mr. Fred M. Walker, for fourteen years general superintendent of the Duval County Hospital in Jacksonville, Fla., is administrator, and Dr. Brodie C. Nalle, Charlotte, is president and chief of the medical staff. Dr. Paul Kimmelsiel, recently associate professor of pathology at the Medical College of Virginia, Richmond, has been appointed pathologist and Dr. Allan Tuggle, instructor in radiology at Cornell University Medical College, is the radiologist. There will be a resident staff of eight physicians. Funds for the new hospital were assembled by a PWA grant of \$450,000, a \$350,000 bond issue, a subscription campaign that raised \$135,000 and contributions from a number of other sources. The present institution represents a merger of the former St. Peter's Hospital and the Good Samaritan.

OHIO

Personal.—Dr. Russell B. Crawford has been selected to head the Lakewood City Hospital, Lakewood, succeeding Miss Elizabeth Harding, who resigned, effective September 1.—Dr. Lyman F. Huffman, Cleveland, has been appointed a member of the Ohio Public Health Council to succeed Dr. Clyde L. Cummer, Cleveland, resigned.—Dr. Charles C. Crosby, Ashtabula, has been appointed health officer of Ashtabula County, succeeding Dr. Jonas L. Hurst, Dorset.

Rachford Memorial Lectures.—Dr. James S. Plant, Newark, N. J., delivered the ninth annual series of Benjamin Knox Rachford Memorial Lectures at the Children's Hospital, Cincinnati, October 17-18. Dr. Plant's subjects were "Infection Points in the Field of Behavior" and "Negativism, Its Treatment and Its Implications." The Rachford Lecture-ship was established by friends of Dr. Rachford to commemorate his many years of service to the University of Cincinnati College of Medicine and to the practice of pediatrics.

Postgraduate Day in Toledo.—The seventh annual Postgraduate Day of the University of Toledo will be presented, November 1, at the university. The guest speakers will be Drs. John S. Lockwood and Harrison F. Flippin of the faculty of the University of Pennsylvania School of Medicine, Philadelphia. Dr. Lockwood's subjects will be: History and Mode of Action of Sulfanilamide. Chemotherapy in Special Surgical Infections, Orogenic Infections and Meningitis; Septicemia; Cellulitis. Chemotherapy in Prophylaxis and Treatment of Traumatic Wounds, Pyoperic Infections and Peritonitis.

Dr. Flippin will speak on the following topics: Pharmacology, Method of Administration and Toxicity of Sulfonamides. Chemotherapy in Special Medical Infections (Urinary Tract, Scarlet Fever, Rheumatic Fever, Endocarditis, Malaria). Chemotherapy of Respiratory Disease.

PENNSYLVANIA

Personal.—Dr. George B. Woods, Washington, 90 years old, received the degree of bachelor of science from Waynesburg College in September. A member of the class of 1872, Dr. Woods left college to enter medical school.—Robert L. Harding, D.D.S., formerly of Ann Arbor, Mich., has been appointed director of the department of oral and maxillofacial surgery at the Geisinger Memorial Hospital, Danville, it is reported.

Philadelphia

Hospital News.—Mercy Hospital presented its first symposium on diseases of the rectum, October 22. Among the speakers were Drs. Collier F. Martin, Harry E. Bacon and Thomas R. Peyton.

Dinner in Honor of Retiring Teachers.—The Medical Alumni Association of Temple University sponsored a dinner at the Union League Club, October 2, in honor of Drs. Frank C. Hammond, who recently retired as professor of gynecology, and Jesse O. Arnold, who retired as professor of obstetrics. Dr. William N. Parkinson, dean of the medical school and president of the alumni association, presided; the speakers included Charles E. Beury, L.L.D., president of the university; Drs. Charles H. Henninger, Pittsburgh, then president of the Medical Society of the State of Pennsylvania; Francis F. Bortz, then president-elect of the state society; Edward L. Wilmer Krusen and William Wayne Babcock.

Pittsburgh

Personal.—Dr. Oliver E. Turner has been appointed in charge of a new health district for Allegheny County outside of Pittsburgh, with offices in the Falk Clinic.

Hospital News.—Mercy Hospital presented its annual "Mercy Day" program, September 26, with Dr. Esmond R. Long, Philadelphia, as the speaker on "Diagnosis of Chronic Diseases of the Chest in the Light of the Pathologic Anatomy."

Symposium on Vertigo.—At a meeting of the Allegheny County Medical Society, October 15, a symposium on vertigo was presented, with the following speakers: Drs. Harold L. Mitchell and John A. Malcolm, on the neurologic and medical aspects; John F. McCullough and Leslie H. Osmond, on roentgenologic interpretations; Robert J. Billings and Charles W. Fischer, the ophthalmologic point of view; Nathaniel A. Weisser, the ophthalmologic point of view; Samuel F. Grunnagle, cerebral and cerebellar aspects.—Drs. John J. McAleese and Charles F. Elterich addressed the Pittsburgh Pediatric Society, October 18, on "Use of Zinc Oxide and Oil of Cloves Paste in the Treatment of Osteomyelitis" and "Sonne Dysentery" respectively.

SOUTH CAROLINA

Society News.—Dr. Joseph Decherd Guess, Greenville, was elected president of the Piedmont Post-Graduate Clinical Assembly at the annual meeting in Anderson in September, succeeding Dr. Edgar A. Hines, Seneca. Vice presidents elected were Drs. Joseph M. Feder, Anderson; James C. Harper, Greenwood; Benager C. Teasley, Hartwell, Ga., and Robert A. Ross, Durham, N. C. Dr. Archer L. Smethers, Anderson, was reelected secretary.

TENNESSEE

Society News.—Dr. Hedy S. Shoulders, Nashville, addressed the Davidson County Medical Society, Nashville, September 3, on "Gastrointestinal Roentgenology: An Analysis of Findings Over a Twenty Year Period." Speakers September 10 were Drs. Duncan E. and Rollin A. Daniel Jr. on "Fractures of the Shaft of the Humerus."—At a meeting of the Chattanooga and Hamilton County Medical Society, September 5, the speakers were Drs. Samuel H. Long on "Allergy and the Eye, Ear, Nose and Throat," and Oliver L. Von Canon, "Anemias of Childhood."—At a meeting of the Dyer, Lake and Crockett Counties Medical Society, Dyer, September 4, the speakers, all of Dyersburg, were Drs. Jesse Paul Baird, on "Unusual Types of Intestinal Obstruction in Infancy"; Orren B. Landrum, "Parasagittal Meningioma and Multiple Myeloma of the Skull," and William F. Anderson, "Pernicious Anemia."

TEXAS

Public Health Meeting.—The annual meeting of the Texas Public Health Association was held in Fort Worth, September 30 to October 2, under the presidency of Dr. George A. Gray, Sweetwater. The speakers included Drs. Joseph W. Mountin, U. S. Public Health Service, Washington, D. C., on "The Complications of Regional Differences in Texas"; Frederick R. Lummis, Houston, "The Present Public Health Status of Heart Disease," and Frances C. Rothert, regional consultant, U. S. Children's Bureau, New Orleans, "Recent Developments in Maternal and Child Health Programs." Dr. Clarence Burke Brewster, Fort Worth, was chosen president-elect.

VIRGINIA

Annual Lectures in Richmond.—The third annual series of lectures has been announced by the Richmond Academy of Medicine. The first lecture was presented October 22 by Rolland J. Main, Ph.D., Richmond, on "Integration and Terminology of the Endocrine System." The remainder of the series will be:

- Dr. Harry B. Van Dyke, New Brunswick, N. J., Physiological Studies of the Anterior Pituitary Gland, November 19.
- Edgar Allen, Sc.D., New Haven, Conn., Puberty and the Menstrual Cycle, January 21.
- Dr. Willard M. Allen, St. Louis, Endocrine Therapy of Abnormal Menstruation and the Menopause, February 4.
- Dr. Edwin C. Hamblen, Durham, N. C., Sterility and Pregnancy from an Endocrinological Standpoint, February 18.
- Dr. John Eager Howard, Baltimore, Androgens and Androgenic Therapy, March 11.

GENERAL

Sedgwick Medal Awarded Posthumously to Dr. Zinsser.—The Sedgwick Memorial Medal of the American Public Health Association was awarded posthumously, October 8, to Dr. Hans Zinsser. At the time of his death, Dr. Zinsser was professor of bacteriology and immunology at Harvard Medical School, Boston.

Health Council Agencies Move.—The National Tuberculosis Association is moving its offices during October from Rockefeller Center to 1790 Broadway. According to the October *Bulletin* of the association, other members of the National Health Council that have also been in Rockefeller Center will move to the Broadway address.

Refresher Series on Radiology.—The Radiological Society of North America, Inc., has announced a refresher series to be conducted at the Hotel Statler, Cleveland, December 1-6. It will be the third annual course to be offered as a part of the annual meeting of the society. Additional information may be obtained from Dr. Lewis G. Allen, 905 North Seventh Street, Kansas City, Kan.

Fellowship Fund in Memory of Dr. Brown.—Friends of the late Dr. Lawrason Brown, for many years head of the Trudeau Sanatorium, Saranac Lake, N. Y., have established the Lawrason Brown Memorial Fund to finance one or more fellowships for research in diseases of the chest. The fund will be managed by the Saranac Lake Society for the Control of Tuberculosis, and if at any time that organization should cease to exist the management of the fund will be offered first to Johns Hopkins University. The present committee is composed of Drs. Leroy U. Gardner and James Woods Price, Saranac Lake; Louis Hamman, Baltimore; Esmond R. Long, Philadelphia; David R. Lyman, Wallingford, Conn., and William P. Thompson, New York.

Brinkley Loses Libel Suit.—The New York Times for October 15 noted that the U. S. Supreme Court denied Dr. John R. Brinkley a review of the decision of the United States Fifth Circuit Court of Appeals on his case against Dr. Morris Fishbein, Editor of THE JOURNAL. The basis of the suit was an article in *Hygeia* entitled "Modern Medical Charlatans," and reference was made to the denial of the Fifth Circuit Court of Appeals in New Orleans in THE JOURNAL, April 27, page 1682. The case was originally tried in the Federal Court of the Western District of Texas, in which the jury returned a verdict for the defendant (THE JOURNAL, April 8, 1939, p. 1346). Brinkley then appealed to the Circuit Court of Appeals and subsequently to the Supreme Court. Both appeals resulted in denial of reviews.

Fellowships in Psychoanalysis.—The Boston Psychoanalytic Institute announces three additional Sigmund Freud Memorial Fellowships for Psychoanalytic Training, to begin September 1941. These fellowships are open to graduates of a recognized medical school who have had at least one year of general hospital training and two years' work in psychiatry and covers tuition fees only. One additional fellowship for training in applied nontherapeutic psychoanalysis will be open

to those who have a doctor of philosophy degree or an equivalent degree in the field of anthropology, sociology, pedagogy and so on. Further information may be obtained from Dr. Moses Ralph Kaufman, chairman of the educational committee, Boston Psychoanalytic Institute, 82 Marlborough Street, Boston. Applications close on February 1.

Bequests and Donations.—The following bequests and donations have recently been announced:

- University of Pennsylvania, a trust fund of \$40,000 and Rush Hospital, Philadelphia, \$5,000 for treatment and study of diseases of the digestive system by the will of Mrs. Mary Hawley Thompson, Media, Pa.
- Jewish Hospital, Philadelphia, \$198,519 to build a nurses' home as a gift from the late Mary S. Hirsh.
- Emergency Hospital, Washington, D. C., \$50,000 by the will of the late Mrs. May Palmer Depew.
- Presbyterian, Northeastern, Episcopal and Frankford hospitals, Philadelphia, and Abington Memorial Hospital, Abington, Pa., \$10,000 each by the will of the late Charles P. Cochran.
- Presbyterian Hospital, Chicago, \$10,000 by the will of the late Warren A. Lamson.
- Lenox Hill Hospital, New York, \$3,000 by the will of the late Mrs. Ida Welz.
- New York Medical College and Flower and Fifth Avenue Hospitals, \$242,531 from the estate of Mrs. Helen S. Case.
- Germantown Hospital, Germantown, Pa., \$10,000 to endow two beds, by the will of Miss Mary McCullagh.
- International Cancer Research Foundation, Philadelphia, will receive the greater part of an estate of \$265,000 left by Mrs. Gertrude Wellington.

Pan American Congress of Ophthalmology.—Permanent organization of a Pan American Congress of Ophthalmology was effected at the first meeting of the congress in Cleveland, October 11-12. Dr. Harry S. Gradle, Chicago, was elected president; Dr. Conrad Berens, New York, executive secretary for North America and Dr. Moacyr E. Alvaro, São Paulo, Brazil, for the Latin American countries. Vice presidents elected were: Drs. Frank Brawley, Chicago; Samuel Hanford McKee, Montreal, Canada; Edward Jackson, Denver; Tomás R. Yanes, Havana, Cuba; A. Vasquez-Barriera, Montevideo, Uruguay; José Pereira Gomes, São Paulo, Brazil, and Enrique Demaria, Buenos Aires, Argentina. It is expected that the next congress will be held in Montevideo in 1943. About twenty Latin Americans attended the congress, representing Brazil, Costa Rica, Cuba, Chile, Colombia, Guatemala, Panama and Puerto Rico. The congress was sponsored by the American Academy of Ophthalmology and Otolaryngology.

Society of Obstetrics and Gynecology.—The Pacific Coast Society of Obstetrics and Gynecology will hold its ninth annual meeting in San Francisco, November 6-9, under the presidency of Dr. Alice F. Maxwell, San Francisco. Papers will be presented by:

- Dr. Gordon G. Thompson, Seattle, Wash., Fibroids in Pregnancy.
- Dr. Arthur B. Nash, Victoria, B. C., Manchester Operation.
- Dr. Paul A. Glibe, San Francisco, Dyspareunia and Related Somatic Manifestations.
- Dr. John C. Irwin, Los Angeles, Extraperitoneal Cesarean Section: A Modification of Latzko Technic with Report of Thirty Cases.
- Dr. Donald G. Tollefson, Los Angeles, Anesthesia and Analgesia in Labor.
- Drs. William Benbow Thompson and Emil J. Krahulik, Los Angeles, Fetal Resuscitation.
- Dr. Hervey K. Graham, San Diego, Routine Chest Roentgenograms in Pregnancy: A Study Based on 800 Consecutive Cases.
- Dr. Olin M. Holmes, San Mateo, High Protein Diet in Pregnancy.
- Drs. Daniel G. Morton and Charles Thomas Hayden, San Francisco, Incidence of Ovulation as Determined by Endometrial Biopsies.
- Dr. Bernard J. Hanley, Los Angeles, Pregnancy and Syphilis.
- Dr. Erle Henriksen, Los Angeles, Resection of the Superior Hypogastric Plexus.

Government Services

Applications Closed for Temporary Medical Officers
—Permanent Positions Still Open

The U. S. Civil Service Commission announces that applications are closed for temporary and part time civilian medical officers in connection with expansion of the U. S. Army, as enough have been received to supply prospective needs.

The commission calls attention to the fact, however, that there is an urgent need for medical officers and senior and associate medical officers to fill permanent positions in other agencies. These positions pay from \$3,200 to \$4,600 a year and include fourteen specialized branches of medicine. There is also need for junior medical officers at St. Elizabeths Hospital, Washington, D. C., at \$2,000 a year. Information and application forms may be obtained at the office of the board of civil service examiners at any first or second class postoffice or from the U. S. Civil Service Commission, Washington, D. C., or from any of the commission's district offices.

Foreign Letters

LONDON

(From Our Regular Correspondent)

Sept. 28, 1940.

The Bombing of London Hospitals

The indiscriminate bombing of London has involved several hospitals, as many as three in one night. In one case a high explosive went straight through the glass dome, crashed through a five story staircase and landed on the ground floor. Fortunately there was only one casualty, a doctor who was working in his office. The desk in front of him disappeared and he remained perched on his chair near the wall with a 50 feet chasm in front of him. Despite a badly cut head he was rescued by firemen alive. When nurses opened the doors of the various wards they found a yawning abyss in front of them. The staff worked heroically getting 100 patients to the ground floor by an emergency method. Some were slid down a wooden ramp which had been put up only the day before. Others were carried down fire escapes. Among the patients were thirty casualties from previous air raids. Two more bombs fell on the works department. Though stricken, the hospital carried on. While the patients were being evacuated, four air raid casualties from the area were dealt with and one serious operation was performed.

In another attack doctors and defense workers carried on in the street while bombs were falling and a direct hit occurred on a nearby shelter containing 1,000 people. The injured were attended to in the street in the glare of the flame-lit sky and transferred to waiting ambulances while the bombers droned above. Among fourteen killed by this one bomb were mothers and children. Working in the light of fires and carefully shielded torches, doctors improvised tourniquets and dressed wounds.

The largest of the hospitals, the London, has been bombed several times. The two hundredth anniversary of its foundation has just been passed. The king sent a message of congratulation in which he expressed admiration for the way in which the medical and nursing staffs are carrying on in spite of the repeated bombing. He visited the hospital and, with the queen, they walked through the four wards set aside for air raid casualties, where injured men and women told them of their adventures.

The hospitals are working under new conditions. Their ordinary patients have been removed to safer localities and they are being used for the treatment of air raid casualties, which are dealt with in the first instance by an ambulance service organized for the purpose before the outbreak of war. Great demands have been made on this service as well as on the auxiliary fire department organized to cooperate with the regular fire department in dealing with the fires produced by incendiary bombs. The experiences of the last few weeks have shown the soundness of these services, which consist of volunteers trained for the purpose. They have shown an excellent spirit and worked with great devotion. They have suffered air-raid casualties, of which some have been fatal. The ambulance service has had to transport many air raid casualties to the hospital and in spite of the blackout the average time taken to reach a casualty has been only seven minutes from the receipt of the call. Casualties among the personnel have been numerous. The London County Council is providing for persons rendered homeless by air raids rest centers, bedding and hot meals.

Four Physicians Killed in London Air Raids

During the daily indiscriminate bombing of London, physicians, like other citizens, carry on. At a meeting of the London Insurance Committee (the body which controls the administration of panel practice) it was reported that as the result of air raids the offices of many London insurance practitioners had

been demolished or put out of action. Four physicians have lost their lives. In one case the wife, daughter and maidservant of the physician were killed with him. An appeal made to physicians to stand by their unfortunate colleagues and carry on their work had met with the readiest response. Panel physicians had agreed to attend any insured persons, whether on their lists or not. In view of the depletion by war service of physicians available for civilian service, it was decided to increase the maximum of persons allowed on a physician's list by 5 per cent.

United States Medical Unit in England

An advance party of an American hospital foundation has arrived in England and will proceed to London after seeing some hospital arrangements in the Northwest. Mr. Harry Platt, one of the Ministry of Health's consultants in orthopedic surgery, who has acted as link between the ministry and trustees in America, states that American sympathizers with Britain who want to help in the treatment of war injuries have established a foundation, duly incorporated as a charity, like the Rockefeller and Carnegie trusts, with the object of providing, if need be, 1,000 beds free to this country. The leading spirit is Dr. Philip Wilson, professor of orthopedic surgery at Columbia University College of Physicians and Surgeons, who was in France in 1915 with the American Ambulance, joined the Harvard unit at a British hospital and later served with the American Expeditionary Forces. Dr. Wilson enlisted the help of American well wishers in many towns for his scheme and funds came in rapidly. The financing of the unit is based on the Allied Relief Fund, which theoretically is available for any form of humanitarian work, feeding, medical and so on. The president is Mr. Winthrop Aldrich and the trustees include Mr. A. P. Sloan of General Motors Corporation and Mrs. Alfred Dupont.

Dr. Wilson leads an advance party of seven surgeons, three nurses and two secretaries. The British Ministry of Health, which is responsible for the Emergency Casualty Services, will give the visitors the opportunity of helping in one of its hospitals. If the war becomes more intense and there are many casualties, reinforcements will be sent from America. Possibly the Ministry of Health could then place a hospital at their disposal, but at present our casualties are being steadily discharged from the hospitals and air raid casualties are dispersed all over the country, so a central American hospital is not needed. The members of the party on their arrival could scarcely believe their eyes when they saw the port so completely undamaged and normal. They brought two truckloads of surgical instruments and have \$250,000 for a year's working.

Empty Beds in the War Hospitals

How very different the attack by air on Britain has turned out from what was expected was shown in the House of Commons by Mr. Churchill. More than 150,000 beds were got ready but are still empty. During August 1,075 civilians were killed in Great Britain and a slightly greater number were seriously injured. For a population of 45,000,000 these losses were very small.

Marriages

FRANCIS EDWARD O'NEILL, Sanderson, Texas, to Miss Estella Schellhase of San Antonio, June 25.

BENJAMIN N. SEARCY, Rising Sun, Ind., to Miss Dorothy Means, in Lawrenceburg, June 9.

HAROLD C. BERNSTEIN, Los Angeles, to Miss Barbara Rothchild of Chicago in September.

SIDNEY STILLMAN, New Orleans, to Miss May Goldie Setzer, at Jacksonville, Fla., June 16.

EDWIN LEVER LAME to Miss Mary Massey Perkins, both of Philadelphia, September 7.

WILLIAM A. STUCKEY to Miss Mary Frances Tucker, both of Sumter, S. C., recently.

Deaths

Wilfred Thomason Grenfell, St. Anthony, Newfoundland, founder of the Labrador Medical Mission, died, October 9, at his home in Charlotte, Vt., of heart disease, aged 75. Dr. Grenfell was born Feb. 28, 1865, in England. He was a licentiate of the Royal College of Physicians of London and member of the Royal College of Surgeons of England in 1888. After a period as house physician at London Hospital, he organized a hospital service for the fisheries of the North Sea and cruised with fishermen from the Bay of Biscay to Iceland, establishing homes for them and providing mission services at sea. In 1892 he went to Newfoundland on a small boat fitted out with hospital supplies. That voyage decided Dr. Grenfell's career. During the following winter the governor of Newfoundland invited him to take up regular work along the Labrador coast. Materials were sent out for a hospital unit, to be established 200 miles farther north, and from this grew the International Grenfell Association, which by 1937 had six hospitals, seven nursing stations, four hospital ships, four orphanage boarding schools, fourteen industrial centers, three agricultural stations, twelve clothing distribution centers, a supply schooner and a lumber mill. Dr. Grenfell served in the World War as a major in charge of the medical unit sent by Harvard University. He received honors from colleges in United States and England, among others a Doctor of Laws from Williams College, McGill University, Middlebury College, Princeton, Bowdoin and St. Andrews, and a Master of Arts degree from Harvard. He was awarded a fellowship and the Murchison Bequest of the Royal Geographical Society, a gold medal of the Academy of Social Sciences of North America, and the Livingstone Gold Medal of the Scottish Geographical Society. He was a fellow of the American College of Surgeons. In 1927 he was knighted by King George V; in 1929 he was installed a rector of St. Andrews University in Scotland. He was the author of "Vikings of Today," "Harvest of the Sea," "Off the Rocks," "Adrift on an Ice Pan," "Down to the Sea," "A Labrador Doctor" (autobiography), "Northern Neighbors" and many others.

Ernest A. Pribram ♂ Chicago; Deutsche Universität Medizinische Fakultät, Prague, Czechoslovakia, 1903; formerly professor of pathology at the University of Vienna and assistant professor of pathology at Rush Medical College; clinical professor of clinical microscopy and at various times professor of bacteriology and preventive medicine and professor of medicine at Loyola University School of Medicine; assistant, later assistant director and director of the State Serum Institute, Vienna, from 1907 to 1926; member of the American Association of Pathologists and Bacteriologists, Society of American Bacteriologists and the American Society of Clinical Pathologists and other scientific societies; member of the International Society of Microbiology and in 1930 president of the American Committee on Nomenclature in Paris; corresponding member of the Gesellschaft der Aerzte, Vienna; Deutsche Chemische Gesellschaft, Berlin, and the Austrian Cancer Research Society, Vienna; pathologist to St. Elizabeth's Hospital, Chicago, and St. Therese's Hospital, Waukegan; aged 61; died, September 14, in St. Joseph's Hospital, Lewiston, Mont., of injuries received in an automobile accident.

Alexander Swanson Begg ♂ Boston; Drake University College of Medicine, Des Moines, Iowa, 1907; instructor in pathology at his alma mater from 1907 to 1909, assistant professor of pathology, histology and embryology, 1909-1910, and professor of histology and embryology from 1910 to 1913; teaching fellow at Harvard Medical School, 1911-1912, and at various times instructor in comparative anatomy, dean of the graduate school of medicine and demonstrator in anatomy and instructor of histology; research associate at the Carnegie Institution, 1915-1916; dean and Waterhouse professor of anatomy at the Boston University School of Medicine; served during the World War; member of the executive council of the Association of American Medical Colleges from 1929 to 1932; past president of the Norfolk District Medical Society; member and formerly on the executive committee of the National Board of Medical Examiners; member of the American Association of Anatomists; since 1935 secretary of the Massachusetts Medical Society; recently state chairman of the medical preparedness committee in Massachusetts; aged 59; died, September 26, of coronary thrombosis.

William Augustus Howe, Phelps, N. Y.; College of Physicians and Surgeons, medical department of Columbia College, New York, 1888; member of the Medical Society of the State

of New York; past president of the Ontario County Medical Society; formerly county coroner; for many years health officer; deputy commissioner of health of New York State from 1910 to 1914; chief of the medical inspection bureau of the state education department from 1915 to 1934; director, division of communicable diseases, state department of health, in 1909; past president of the child hygiene section of the National Education Association; one of the founders of the American Association of School Physicians, of which he was president, 1927-1928; in 1929 was awarded the Ling Foundation Medal for distinguished service to child health; editor of the *School Physicians' Bulletin* from 1930 to 1937; aged 78; died, September 11, in the Clifton Springs (N. Y.) Sanitarium, of cerebral thrombosis and arteriosclerosis.

Joseph McIver ♂ Philadelphia; University of Texas School of Medicine, Galveston, 1912; member of the American Neurological Association; past president of the Philadelphia Neurological Society; commissioned lieutenant in the U. S. N. R. F. in 1917, serving as neuropsychiatrist at the United States Naval Hospital, League Island, until June 1919; formerly instructor and associate in neurology at the University of Pennsylvania School of Medicine; chief neurologist to Misericordia, Fitzgerald-Mercy and Nazareth hospitals; chief of the neuropsychiatric staff of the Philadelphia General Hospital; neuropsychiatrist to the House of Detention of Philadelphia; aged 53; died, September 7, in Bryant, Texas, following an operation for appendicitis.

Abraham Louis Levin ♂ New Orleans; Medical Department of Tulane University of Louisiana, New Orleans, 1907; clinical professor of medicine, Louisiana State University School of Medicine; member of the National Gastroenterological Association; past president of the Louisiana Society of Gastroenterology; served during the World War; on the staffs of the Touro Infirmary, Hotel Dieu and the Charity Hospital; aged 59; died, September 15, of coronary occlusion.

Hermann J. G. Koobs ♂ Rogers, Ark.; Northwestern University Medical School, Chicago, 1902; past president of the South Dakota State Medical Association; member of the House of Delegates of the American Medical Association in 1919; member of the American Academy of Ophthalmology and Otolaryngology; aged 71; died, September 3, of diverticulitis with perforation of the colon.

Charles Robinson Hume, Anadarko, Okla.; University of Michigan Department of Medicine and Surgery, Ann Arbor, 1874; member of the House of Delegates of the American Medical Association, 1918-1919; member and past president of the Oklahoma State Medical Association; past president of the Caddo County Medical Society; formerly county health officer; aged 92; died, August 9.

Charles Spalding Hunt ♂ New York; Columbia University College of Physicians and Surgeons, New York, 1905; professor of anesthesia at the New York Polyclinic Medical School and Hospital; member of the American Society of Anesthetists; on the staff of St. John's Hospital and the Long Island College Hospital; aged 65; died, September 9, in the Polyclinic Hospital.

Oscar Richardson, Lakeville, Mass.; Harvard Medical School, Boston, 1900; member of the Massachusetts Medical Society and the American Association of Pathologists and Bacteriologists; at one time associate medical examiner for Suffolk County; formerly assistant pathologist at the Massachusetts General Hospital, Boston; aged 80; died, August 28.

Thomas Clifford Neal, Anniston, Ala.; Emory University School of Medicine, Atlanta, Ga., 1918; member of the Medical Association of the State of Alabama; at one time district health commissioner of unit number 2, composed of Catoosa, Whitfield, Murray and Gordon counties in Georgia; aged 51; died, September 2, in St. Louis of pulmonary tuberculosis.

Robert Phillips Munson, Medina, N. Y.; Columbia University College of Physicians and Surgeons, New York, 1922; formerly secretary of the Orleans County Medical Society; served during the World War; aged 43; on the staff of the Medina Memorial Hospital, where he died, September 11, of cirrhosis of the liver.

Alexander Ross Alguire, Cornwall, Ont., Canada; McGill University Faculty of Medicine, Montreal, Que., 1905; L.R.C.P., of London, England, and M.R.C.S., England, 1908; fellow of the American College of Surgeons; on the staffs of the Cornwall General Hospital and Hotel Dieu Hospital; aged 55; died, August 29.

George Marion Blickensderfer ♂ Denver; Denver and Gross College of Medicine, 1903; an Affiliate Fellow of the American Medical Association; past president of the staff of

the Children's Hospital; aged 68; died, September 8, of thrombosis of the femoral artery, myocarditis and arteriosclerosis.

Everett E. Watson • Salem, Va.; University College of Medicine, Richmond, 1912; member of the American College of Chest Physicians and the American Association for Thoracic Surgery; medical director of the Mount Regis Sanatorium; aged 52; died, August 3, of pulmonary tuberculosis.

Miles Guthrie Varian, Los Angeles; University of Pennsylvania Department of Medicine, Philadelphia, 1901; aged 67; died, August 12, in the Huntington Memorial Hospital, Pasadena, Calif., of incisional hernia, partial intestinal obstruction, bronchopneumonia and acute myocarditis.

Frederick Rice Waldron, Ann Arbor, Mich.; University of Michigan Department of Medicine and Surgery, Ann Arbor, 1901; past president of the Washtenaw County Medical Society; on the staff of St. Joseph's Mercy Hospital; aged 64; died, August 30, of coronary heart disease.

Addison May Rothrock, Kerrville, Texas; University of Pennsylvania Department of Medicine, Philadelphia, 1893; veteran of the Spanish-American and World wars; aged 70; died, September 1, in the Veterans Administration Facility, Legion, of tuberculosis.

Theodore John Redelings, San Diego, Calif.; Chicago Medical College, 1887; member and past president of the State Medical Society of Wisconsin; past president of the Marinette County Medical Society; at one time city health officer; aged 77; died, September 4.

Edmund Francis Walsh, Boston; Harvard Medical School, Boston, 1908; member of the Massachusetts Medical Society; served in various capacities on the staff of the Boston City Hospital; aged 58; died, August 20, of coronary occlusion, while bathing.

Albert Salomon Hoheb • Rutherford, N. J.; University of Maryland School of Medicine, Baltimore, 1921; served during the World War; aged 47; on the staff of the Passaic (N. J.) General Hospital, where he died, September 13, of chronic myocarditis.

Yetta Scheftel, Chicago; Rush Medical College, Chicago, 1921; clinical instructor of neurology at her alma mater; aged 56; on the staff of the Women's and Children's Hospital, where she died, September 9, of peritonitis and carcinoma of the uterus.

James Krom • Saugerties, N. Y.; College of Physicians and Surgeons, medical department of Columbia College, New York, 1892; for many years health officer and medical inspector of the schools; aged 71; died, September 4, in the Kingston (N. Y.) Hospital.

George Pinckney Reid, Forest City, N. C.; University College of Medicine, Richmond, 1895; member of the Medical Society of the State of North Carolina; at one time bank president; formerly county coroner; aged 78; died, September 8.

Frederick Sumner Briggs • Brandon, Vt.; Columbia University College of Physicians and Surgeons, New York, 1907; served during the World War; formerly member of the school board and health officer; aged 58; died, September 8.

Thomas William Fields, Dresden, Tenn.; Kentucky School of Medicine, Louisville, 1890; University of Nashville (Tenn.) Medical Department, 1902; formerly mayor; served during the World War; aged 76; died, September 4, of carcinoma.

Danforth C. Cowles • Fullerton, Calif.; University of Minnesota Medical School, Minneapolis, 1901; veteran of the Spanish-American War; past president of the Orange County Medical Society; aged 66; died, August 28.

Albert Frederick Hanlon, Greenwich, Conn.; Hahnemann Medical College and Hospital of Philadelphia, 1907; on the staff of the Greenwich Hospital; aged 57; died, September 9, of arteriosclerosis and coronary occlusion.

William Simmons, Lakeville, Conn.; Long Island College Hospital, Brooklyn, 1891; at one time on the staffs of the Brooklyn Eye and Ear, Kings County and Jewish hospitals, Brooklyn; aged 80; died, September 6.

Louis Gilbert Newman, Westfield, N. J.; New York Homeopathic Medical College and Hospital, 1895; aged 67; died, September 9, in the Muhlenberg (N. J.) Hospital of arteriosclerosis and bronchopneumonia.

Eugene Chester Seawright, Fayetteville, Ga.; University of the South Medical Department, Sewanee, Tenn., 1904; formerly mayor; aged 59; died, September 2, in a hospital at Atlanta of carcinoma of the pancreas.

Carroll Colby Burpee, Malden, Mass.; Boston University School of Medicine, 1896; served during the World War; formerly chairman of the board of health; aged 67; died, September 10, of cardiac decompensation.

Boris Gordon Glasgow, Bridgeport, Conn.; University of Moscow Faculty of Medicine, Moscow, Russia, 1896; served in the Japanese, Balkan and World wars; aged 71; died, September 6, in St. Vincent's Hospital.

Franklin Pierce Russell, Akron, Ohio; Charity Hospital Medical College, Cleveland, 1880; aged 87; died, September 5, in the City Hospital of coronary thrombosis and hemorrhage due to varicose veins of the larynx.

Burton Clarence Rumbel, Conyngham, Pa.; Medico-Chirurgical College of Philadelphia, 1905; member of the Medical Society of the State of Pennsylvania; aged 65; died, September 3, of cardiorenal disease.

Bartholomew Maxwell Howley • New Brunswick, N. J.; University of the City of New York Medical Department, 1894; formerly on the staffs of the Middlesex and St. Peter's hospitals; aged 69; died, September 2.

Clarence Abraham Ihle, Dayton, Ohio; Medical College of Ohio, Cincinnati, 1902; veteran of the Spanish-American War; aged 62; died, September 7, in the Miami Valley Hospital of coronary occlusion.

Ludwig Oulmann • New York; Julius-Maximilians-Universität Medizinische Fakultät, Würzburg, Bavaria, 1898; on the staff of the Lenox Hill Hospital; aged 65; died, September 16, of heart disease.

George Bruce Barrow, Staunton, Va.; Medical College of Virginia, Richmond, 1910; member of the Medical Society of Virginia; on the staff of the Western State Hospital; aged 55; died, September 1.

Patterson East, Lafayette, Tenn.; University of Tennessee Medical Department, Nashville, 1891; member of the Tennessee State Medical Association; aged 77; died, August 25, in a hospital at Nashville.

William David Peckham • Utica, N. Y.; Baltimore Medical College, 1897; at one time state senator; formerly health officer and coroner; aged 65; died, September 9, of coronary thrombosis.

Louis W. Satterlee, Alexandria, Minn.; Hahnemann Medical College and Hospital, Chicago, 1894; for many years health officer; aged 84; died, August 30, of cerebral hemorrhage and arteriosclerosis.

James Huff McCurdy, Springfield, Mass.; University of the City of New York Medical Department, 1893; aged 74; died, September 4, in the Springfield Hospital of carcinoma of the bladder.

Jennie A. Beardsley • Chicago; College of Physicians and Surgeons, Keokuk, Iowa, 1895; formerly on the staffs of the Jackson Park and Englewood hospitals; aged 73; died, September 13.

Abram Everett Frye, Youngstown, Ohio; College of Medicine and Surgery, Chicago, 1903; member of the Ohio State Medical Association; aged 69; died, September 3, of arteriosclerosis.

Arthur C. Byas, Memphis, Tenn.; Meharry Medical College of Walden University, Nashville, 1914; aged 57; died, July 28, in the Collins Chapel Connectional Hospital of acute gastritis.

Frank Marion Hall, Sylvan Beach, N. Y.; Baltimore Medical College, 1897; town health officer and school physician; aged 68; died, September 6, in the Main Street Hospital, Oneida.

Kristian Egilsrud, Minneapolis; Kongelige Frederiks Universitet Medisinske Fakultet, Oslo, Norway, 1892; aged 72; died, August 31, of pulmonary embolus and carcinoma of the tongue.

Theodore Julius Yetina Miller, Fords, N. J.; Long Island College of Medicine, Brooklyn, 1934; member of the Medical Society of New Jersey; aged 31; died, September 4.

John Duff McBarron • New York; College of Physicians and Surgeons, medical department of Columbia College, New York, 1892; aged 73; died, August 25, in St. Luke's Hospital.

Henry George Cameron, Weyburn, Sask., Canada; McGill University Faculty of Medicine, Montreal, Que., 1924; on the staff of the Weyburn Mental Hospital; aged 44; died, August 6.

Matthew Bunyan Cameron, Eutaw, Ala.; Medical College of Alabama, Mobile, 1886; member of the Medical Association of the State of Alabama; aged 79; died, August 25.

George Benjamin Baylis Jr., Collins, Miss.; University of Tennessee Medical Department, Nashville, 1925; aged 43; died, August 27, in the Methodist Hospital, Hattiesburg.

John Riordon Ⓢ Rutherford, N. J.; University of Buffalo School of Medicine, 1893; for many years on the staff of St. Mary's Hospital, Passaic; aged 72; died, September 2.

Albert P. Kittle, Newton, Ill.; Barnes Medical College, St. Louis, 1904; aged 69; died, September 12, in the Olney (Ill.) Sanitarium of myocarditis and endocarditis.

Rudolph Angus Nichols Sr., Richmond, Va.; Medical College of Virginia, Richmond, 1895; member of the Medical Society of Virginia; aged 67; died, September 6.

Enoch Wilson Baxter, Moyock, N. C.; College of Physicians and Surgeons, Baltimore, 1887; member of the Medical Society of Virginia; aged 79; died, August 10.

Clarence Edward Ressler, Anthony, Kan.; Hahnemann Medical College and Hospital, Chicago, 1896; aged 68; died, July 16, of arteriosclerosis and hypertension.

E. Agnes Scott Brandon, Denver; Denver College of Physicians and Surgeons, 1909; member of the Colorado State Medical Society; aged 76; died, August 13.

Isaiah Frank, New York; New York University Medical College, New York, 1898; aged 64; died, September 14, in the Flushing (N. Y.) Hospital of pneumonia.

Henry Joseph Niebauer, Madison, Wis.; University of Wisconsin Medical School, Madison, 1934; aged 30; was drowned, August 20, in Lake Mendota.

Stephen Yerkes Van Meter, Los Angeles; University and Bellevue Hospital Medical College, New York, 1904; aged 64; died, July 10, of coronary thrombosis.

Judson N. Woodworth, Santa Monica, Calif.; Hahnemann Medical College and Hospital, Chicago, 1878; Civil War veteran; aged 97; died, August 20.

John McE. Ward, Philadelphia; Hahnemann Medical College and Hospital of Philadelphia, 1891; aged 77; died, August 30, in the Jewish Hospital.

Anthony White, Greenville, S. C.; Atlanta (Ga.) Medical College, 1894; member of the South Carolina Medical Association; aged 70; died, August 21.

Charles Ware, Orange City, Fla.; College of Physicians and Surgeons, medical department of Columbia College, New York, 1883; aged 87; died, August 29.

Linwood H. Dorr, Dresden Mills, Maine; University of Vermont College of Medicine, Burlington, 1889; aged 74; died, July 13, of chronic nephritis.

Philip A. Hoffmann, Campbellsport, Wis.; State University of Iowa College of Medicine, Iowa City, 1887; aged 87; died, August 29, of bronchiectasis.

Henry Bowen Frazier, Bluefield, Va.; College of Physicians and Surgeons, Baltimore, 1897; aged 68; died, August 9, in the Bluefield Sanitarium.

Frank L. Van Gorder, Coffeyville, Kan.; University Medical College of Kansas City, Mo., 1907; aged 73; died, August 20, at Torch Lake, Mich.

George Houghton Clapp Ⓢ Erie, Pa.; Jefferson Medical College of Philadelphia, 1907; served during the World War; aged 56; died, August 21.

Bureau of Investigation

THE VOGUE SPECTACLE COMPANY FRAUD

Chicago Eyesight Swindle Barred from the Mails

Among the cruellest of frauds are those which trifle with the precious organs of sight. Some of these, whether involved in Post Office fraud orders or otherwise, have previously been dealt with in this department of *THE JOURNAL*. Among them have been "eyesight normalizers," courses in "eye exercises" and simple spectacles-by-mail schemes.

The Vogue Spectacle Company of Chicago was the brain child of one Irving Silvers, who, according to the memorandum on the Post Office investigation, advertised under this trade style the correction of eyesight deficiencies. The alleged simplicity of ordering glasses from him by mail and the pretended benefits to be gained by taking up his "bargain" offer were played up in this specimen advertisement quoted in the memorandum:

FIT YOUR OWN EYEGLASSES FREE

14 TRIAL LENSES FREE!	(Cut of eye-glasses)	SAVE MORE THAN HALF	(Cut of woman wearing glasses)
It's easy to fit your own eyeglasses by our simple		Get the 14 trial lenses FREE. Write today.	

improved method. Save More Than Half. Read small print—do close work—see far and near without eyestrain. We send you complete eye testers FREE.

SEND NO MONEY • 10 DAYS' TRIAL

WEAR VOGUE EYEGLASSES for 10 days. Get more comfort—look distinctive and smart in appearance. Latest styles priced only \$3.85 and up. Others as low as \$1.98. We guarantee satisfaction or refund money promptly. Broken lenses or frames repaired or replaced at low prices. We will send you FREE 14 trial lenses and illustrations of beautiful distinctive patterns for your selection. We only handle High Grade Single and Double Vision Toric Kryptoc Bifocal Lenses ground into one solid piece of glass.

VOGUE SPECTACLE CO., 3234 Lawrence Ave., DEPT. K90, CHICAGO, ILL."

As the memorandum showed, those who answered received a form letter, printed circular matter, so-called testing charts and two cardboard strips each containing seven pieces of glass to be used by the recipient in testing his eyes in order to determine the particular kind of spectacles needed to correct his vision. The literature, judging from the memorandum's quotations, was the expected claptrap of claims and testimonials and may be passed over without further comment here. The charts for testing the vision consisted of a printed cardboard for close reading and a printed sheet for distance. Also there were elaborate "Directions for Using Eye Tester" by means of two cardboard strip testers, about 9 inches long and 1½ inches wide. As mentioned before, each "tester" contained seven lenses and, of the total fourteen, eleven were plus lenses and three were minus ones.

The foregoing facts were brought out in the memorandum on the case, submitted by Hon. Calvin W. Hassell, Acting Solicitor for the Post Office Department. His report went on to show that two sets of the so-called tester lenses sent out by the Vogue concern to prospective purchasers of spectacles were submitted to the United States National Bureau of Standards for examination and measurement. The expert who measured them is said to have reported that his tests showed that in some instances the lenses were not of the dioptric strength claimed by the promoter, Silvers, or of a uniform strength such as would enable Silvers to determine from the report of the customer's self examination what strength of lens was required. Further, the testimony is said to have shown that a number of the lenses contained in each of the strip testers measured by the Bureau of Standards were so badly centered that their dioptric power could not be measured, and that persons using such devices could not correctly determine or report to the Vogue outfit their selection of lenses according to the instructions. The memorandum showed that twelve persons ranging in age from 24 to 61 years testified as to their self measurement of vision by the "Vogue" system and

that all but one or two were unable clearly or comfortably to read the letters on the "Vogue" distance chart at 10 feet while wearing the glasses that the defendant had sold them under the representation that they would correct the purchasers' vision; most of the witnesses testified that the glasses were uncomfortable for close reading.

A special witness for the government at the hearing of this case was Dr. Hollis U. Maness, Passed Assistant Surgeon for the United States Public Health Service, for which agency he specializes in the refraction of eyes and the prescribing of spectacles. Dr. Maness, the memorandum pointed out, had examined the eyes of the witnesses for distance and reading without glasses and had made a similar test with these persons' own glasses, then a third one with the Vogue concern's glasses and a fourth with physicians' regular testing equipment, including the use of test lenses for ordinary hyperopic, myopic, presbyopic and errors of refraction, together with examinations for the detection and correction of astigmatism, as well as appropriate charts for use with these lenses. In most of these tests Dr. Maness employed a cycloplegic. In every instance, he testified, the glasses furnished by the Vogue Spectacle Company were unsuitable for correcting the vision of the users, even those who were able to read the "Vogue" charts, for the continued use of the spectacles would injure their eyesight. The witnesses who had tried these glasses were all found to be suffering from some degree of astigmatism and this condition, Dr. Maness testified, was not one for which they could examine their eyes by means of the test strips sent out by the defendant company. As 85 per cent of all persons with defective vision are, according to Dr. Maness, astigmatic, it is obvious that this percentage of eyesight sufferers is thus eliminated from the possibility of obtaining relief through the defendant's system.

These and many other salient points were brought out in the testimony of Dr. Maness. One such point was the fallacy of the defendant's claim that the glasses he furnished would relieve headaches caused by defective vision, whereas Dr. Maness showed that such headaches may be due to various eye disorders that cannot be determined by the eye testing methods employed in this scheme or corrected by the spectacles furnished on the basis of such tests. He further pointed out the falsity of the claim that persons unable to read all of the printed matter furnished for the so-called preliminary "quick easy test" need glasses. His testimony showed that the eyes may be involved in many conditions such as vitreous opacity, corneal leukoma or central choroiditis, which could not be corrected by use of lenses.

The medical testimony further demonstrated that, although the promoters of the scheme represented that a "10 days trial" would be sufficient time for the prospect to determine whether the eyeglasses furnished him properly fitted his eyes, this period was not, in fact, adequate for the purpose, since spectacles which might feel comfortable for a while and might apparently relieve symptoms of trouble could eventually prove unsuited to the eyes. The evidence showed that the promoter's claim that the customer "cannot lose" was false, since eye injuries which might follow the use of unsuitable glasses certainly must be considered a loss to the purchasers.

Although the defendant's counsel argued that there was conflict between the medical testimony furnished by the government's expert witness, Dr. Maness, and the affidavit supplied for the defendant company's evidence by Dr. Paul K. Anthony of Chicago, it was brought out that Dr. Anthony had admitted that the company in question could not "correctly fit" or furnish "a perfect fit" in glasses to all persons who apply therefor. As Dr. Anthony did not appear at the hearing and thus was not subject to cross examination, little weight was given to any of his "evidence." According to the records of the American Medical Association Dr. Paul Krvavica Anthony was graduated by Loyola University School of Medicine, Chicago, in 1936 and was licensed to practice in Illinois in the same year. He is shown as a member of his local medical society but not as a Fellow of the American Medical Association. It is on record that his name was Paul Anthony Krvavica until he had it changed to Paul Krvavica Anthony by a court order in October

1937. The Post Office memorandum described him as "an oculist in the employ of the respondent." The concern also was said to have engaged the services of an Andrew H. Gosstron, described as an optometrist.

Altogether there was so much evidence to support the solicitor's charge that the business was a scheme for obtaining money through the mails by means of false and fraudulent pretenses, representations and promises that the Post Office Department, on Oct. 30, 1939, issued the recommended fraud order against the Vogue Spectacle Co., Vogue Spectacle Company and its officers and agents as such.

Correspondence

DIABETES

To the Editor:—In your issue of September 21, Dr. Joslin and his associates have patiently repeated some of the decisive reasons against lax diabetic treatment. Immediately after the discovery of insulin came the first pseudoscientific suggestion of giving enough insulin to provide for metabolism of a requisite amount of food and then letting the patient eat freely without regard to glycosuria or hyperglycemia. I long ago gave up arguments over the persistent repetitions of this error, according to the advice in Proverbs 27:22. As so much of human life and disability are involved, perhaps Dr. Joslin's warning may be reinforced by two summarized case records:

1. A woman aged 55, first seen in 1925, had diabetes, obesity, goiter, hypertension, arteriosclerosis and myocardial degeneration. Diabetes was controlled by reduction of weight from 160 to 140 pounds (from 72.6 to 63.5 Kg.). After five years, onset of hyperthyroidism caused loss of weight to 110 pounds (50 Kg.) and required 20 units of insulin twice daily. Under medical treatment the thyroid intoxication subsided. The patient has consented to avoid fat but has continually transgressed her liberal carbohydrate allowances. Now, weighing 138 pounds (62.6 Kg.), she is only partly sugar free on 104 units of insulin daily. The principal loss of tolerance occurred not with the hyperthyroidism but progressively at other times. She continually complains of pains, weakness and nervous symptoms. She is seen infrequently and consents reluctantly to stricter treatment and increases of insulin because her symptoms are thus definitely relieved.

2. A woman aged 24, seen in 1922, 5 feet 5 inches (165 cm.) tall, had rather mild diabetes and was kept controlled at a weight of 94 pounds (42.6 Kg.) for nearly a year without insulin. She then preferred to gain to 115 pounds (52 Kg.) by taking 24 units of insulin a day. She subsequently gained to 130 pounds (59 Kg.) and required 50 units of insulin daily. Owing to fear of insulin reactions and immunity from diabetic symptoms she departed from the rule of sugar freedom which was maintained prior to insulin. She adopted for herself a plan of convenience which has been endorsed in some clinics, namely that she has glycosuria during the early part of every day. Now, weighing 129 pounds (58.5 Kg.) after years of a low-fat high-carbohydrate diet, she cannot be sugar free with 100 units of insulin daily. Her freedom from discomforts may be explained by her comparative youth, but she has become impressed by the loss of tolerance, so that she may submit to closer supervision.

One man gave me a history of continuous heavy glycosuria for thirty years without treatment or diet restrictions and without any perceptible departure from health, but his ideas were then changed by gangrene. It is thus evident that observations of a few years do not establish the safety of any procedure in a chronic disease. The longest observations in my experience, however, have confirmed the prevention of both

progressiveness and complications under strict control. Contrary to Dr. Tolstoi's recent statement, there has been no change whatever since 1914 in the orthodox ideal of restoring the diabetic as nearly as possible to normal. Abundant testimony from that time to the present establishes this method at least as safe and dependable.

It seems demonstrable that the harm from inadequate treatment is not limited to loss of tolerance. Also it would be wrong to interpret Dr. Joslin's criticism as applicable to only one individual or institution. In an address before the Reizelhausen Foundation in Pittsburgh (Feb. 2, 1940) I mentioned that among the large institutions to which the general medical profession looks for guidance there is a record of ignorance or disregard of proved facts, fads and guesswork announced as brilliant new discoveries and recklessly applied in therapy, exaggerations of the dangers of hypoglycemia, teachings of the necessity or desirability of high blood sugar especially among groups such as cardiac or elderly patients, and unproved claims that certain overbalanced diets will obviate the harmful effects of poorly controlled diabetes on the blood vessels or general system.

The recent confirmation of the undernutrition principle by Dr. Best is not accidental, because the original conclusions were based on scientific proof. Dr. Tolstoi's communication in *THE JOURNAL* of October 12 clearly illustrates how institutions which supposedly stand for science actually practice empiricism. But if an unproved method is to be substituted for a known safe one, to see how it will turn out in practice, it should at least be tried cautiously and within limitations. It is morally indefensible to make wholesale trials on human beings, risking the chance that in twenty years they may prove to have been disastrously mistaken. Also, on this very point of clinical experience, it is noticeable that Joslin's comprehensive long-time statistics have been allowed to stand alone, and the persons and institutions having the greatest material and means for supporting their therapeutic claims by comparable figures have for some reason refrained from doing so. Two statements seem warranted: First, the example of the largest institutions has encouraged laxity among physicians and indirectly among patients. Second, diabetic patients treated just sufficiently to keep them out of acute trouble for a few years constitute the reservoir from which are drawn the great mass of the complications which cause most diabetic deaths today.

I was the first to state that diabetes is not inherently progressive, and also to set up the ideal of normal blood sugar as an index of thorough control of the disease and relief of pancreatic overstrain. As late as 1936 I found myself assigned to a five minute discussion on a program (*Bull. New York Acad. Med.* 12:309, 1936) occupied by speakers from large institutions who unanimously rejected this standard. The adoption by Marks (*M. Clin. North America* 24:649 [May] 1940) of the precise principles and method which I have so long advocated seems to represent a reform in a place where it was as much needed as in the place mentioned by Dr. Joslin. Hyperglycemia must denote an insulin deficit, because it is absent in the normal individual on an identical diet. I have shown that after glycosuria is stopped the amount of extra insulin required to reduce a high blood sugar to normal may be as much as 20 units a day. An important service of modern medicine has been to devise tests for detecting slight deficiencies of vitamins or other food materials and likewise of all endocrine glands and to correct these deficiencies. The sole exception pertains to one of the most vital endocrine products, namely insulin, and it is amazing that there should have been such widespread advocacy of ignoring this manifest deficiency as harmless. Furthermore, it is no more difficult to

treat ordinary cases strictly and keep watch against hyperglycemia than it is to treat them inefficiently and keep watch against dangerous emergencies. Diabetic deaths can be greatly reduced by copying the code of surgeons, namely that both immediate and remote results should be demonstrated and that the practice is open to any physician qualified to produce results up to the accepted standard.

FREDERICK M. ALLEN, M.D., New York.

MYASTHENIA GRAVIS

To the Editor:—In the correspondence columns of *THE JOURNAL*, September 7, page 876, are communications from Drs. Henry R. Viets of Boston and Leo D. Freyberg of Granville, N. Y., commenting on the report of a case of myasthenia gravis which I made in *THE JOURNAL*, July 13, page 123. This gives me opportunity to clarify certain points, as well as to report further progress of the case. Unfortunately for the patient, but fortunately for me, he had a mild return of symptoms at an opportune time.

Concerning the use of quinine, I accept the criticisms of Drs. Viets and Freyberg; their comments may serve to emphasize its contraindications in this condition. The unpleasant effects noted after two days of therapy were nausea, vomiting and ringing in the ears.

Dr. Viets stated that the symptoms as given were consistent with the diagnosis but that it was not clearly indicated that the patient had the primary symptoms of myasthenia gravis, namely fatigue on muscular motion with recovery after rest. This was indicated in the following: "Paresis of the pharyngeal and laryngeal muscles produced a nasal, higher pitched voice, and talking was a decided effort, requiring frequent intervals of rest to avoid development of a whisper. . . . He was able to say but a few words at a time and then had to wait a few minutes before resuming." The weakness of the muscles, always associated with effort followed by recovery on rest, was an outstanding symptom.

On recurrence of his symptoms ten months later he was given 1 cc. of 1:2,000 prostigmine methylsulfate, and he stated that relief of muscle fatigue of the neck and shoulders was noticeable in about twenty-five minutes. The diagnosis of myasthenia gravis was in my opinion such an obvious one that tests such as the reaction of Jolly were not required. Furthermore, according to Wechsler (*Text Book of Neurology*, ed. 3, Philadelphia, W. B. Saunders Company, 1935, pp. 204-205), the reaction may occur in normal persons and is frequently absent in myasthenia gravis; so its value apparently is not great. The weakness of the muscles after the initial effort of contraction was apparent, as was the recovery with rest.

On Aug. 20, 1940, there was a mild return of symptoms. The blood chlorides at this time were 462 mg. of the total chlorides as sodium chloride per hundred cubic centimeters of blood and blood creatinine 2.2 mg. per hundred cubic centimeters of blood. It will be recalled that the patient is a physician and at my request he commented on the progress of his case:

The onset of symptoms was so insidious for from ten to fourteen days that the patient failed to realize the exacerbation of his disease of nearly ten months before. The main symptom was a sensation of heaviness of the head due to fatigue of the neck and shoulder girdle muscles. This was noted within a few minutes of sitting or standing and was relieved shortly after lying down. Prolonged effort merely accentuated the fatigue of the neck and shoulders to the point of an aching pain which required longer rest for relief. Climbing stairs induced a slight to moderate dyspnea. The patient also noted a desire to take naps and sleep longer hours, which he ordinarily never required or indulged in. In other words, at the time of reporting back to Dr. Moehlig his symptoms were not nearly so many or marked as with the initial attack. They were identical, however, as to the insidious onset in muscles supplied by

the cervical plexus, induction with minimal effort, immediate relief on rest, plus an afebrile course with no early gastrointestinal signs or symptoms.

It was decided to give the patient a daily dose of 10 mg. of desoxycorticosterone acetate subcutaneously. For the next week he noted a gradual daily increase in the foregoing symptoms, with beginning anorexia and a loss of faculty to perspire. General weakness increased and the patient voluntarily increased his desoxycorticosterone acetate dose to 10 mg. twice daily. This seemed to just about hold the disease stationary—without improvement. The patient observed, as previously, relief of the neck and shoulder fatigue in about two hours after the injections, and this would last for approximately six hours before he felt poorly again.

Needless to say, the patient was depressed by his recurrence and the prospect of being forced to stop working. He fully appreciated, however, the dramatic and complete prolonged relief of severe symptoms which had followed the previous implantation of desoxycorticosterone acetate. Reading everything procurable on the disease, the physician-patient could easily and early place his syndrome as being that of a typical classic myasthenia gravis. In addition, perusal of the irregular and transitory results of other types of therapy further convinced him of the clinical excellence of desoxycorticosterone acetate implants.

The patient was further encouraged by the following practical observations: The implantation had been performed by placing two unbroken and one inadvertently crushed pellets (totaling 450 mg.) into an abdominal skin and subcutaneous incision. For several months this presented a broad, thin, slightly reddened and elevated, tender scar, typical of an underlying foreign body reaction. In retrospect, the sudden dramatic and continued rapid improvement six days after operation presumably was due to the crushed powdered tablet. The two remaining pellets began to be palpable after a few months. The patient commented that these were becoming more superficial and more easily palpable as time went on, and he thought they were going to extrude themselves gradually. Beginning two months ago, however, the skin scar gradually became white, retracted and insensitive, instead of red, elevated and tender. After a few more weeks recurrence of symptoms began to develop. Obviously all this points strongly to a scar tissue reaction about the pellets, delaying and decreasing absorption of the active substance.

On August 27, ten months since the implantation (Oct. 28, 1939), the scar and subcutaneous tissue containing the pellets was excised. On section two pellets were found; the third which had been broken was completely absorbed. The pellets were about one third their original size and each firmly and completely encapsulated within a cicatrix. The pellets weighed approximately 50 mg. each and since they originally weighed 150 mg., each gave up a total of 100 mg. In the period of 300 days the daily absorption rate was approximately 0.3 mg. per pellet. This corresponds with the observations of Thorn and his associates (Thorn, George; Howard, R. P.; Emerson, Kendall, Jr., and Firor, W. M.: *Treatment of Addison's Disease with Pellets of Crystalline Adrenal Cortical Hormone [Synthetic Desoxycorticosterone Acetate] Implanted Subcutaneously*, *Bull. Johns Hopkins Hosp.* 64:339-366 [May] 1939) of an absorption rate of from 0.25 to 0.3 mg. a day. The two pellets plus two additional ones of 150 mg. each (total 400 mg.) were implanted subcutaneously into the abdominal wall.

The laboratory report on the excised tissue was as follows:

Tissue consists of skin and subcutaneous tissue which included two areas of scar tissue. Microscopic diagnosis: Subcutaneous scar tissue. There is an area of low grade inflammation apparently encapsulating the foreign body.—Plinn F. Morse, M.D.

It has now been fourteen days since the patient was operated on. He continued to take 20 mg. of the desoxycorticosterone acetate daily for three days, then voluntarily reduced this to 10 mg. daily for one week, and for the past four days he has had no injections. He states that he is definitely improved, the improvement being particularly noticeable in the past few days. He has been able to carry on his work in the operating room and in practice with but slight distress and no need of rest periods for the past week.

Time will show whether these improvements were due to the long arm of coincidence or to the therapy. I appreciate the criticisms of Drs. Viet and Freyberg and will conclude with the final paragraph of my paper: "Naturally, further experiences with other patients as well as the continued progress of this patient is desirable before final conclusions concerning lasting benefits are made."

ROBERT C. MOEHLIG, M.D., Detroit.

Queries and Minor Notes

THE ANSWERS HERE PUBLISHED HAVE BEEN PREPARED BY COMPETENT AUTHORITIES. THEY DO NOT, HOWEVER, REPRESENT THE OPINIONS OF ANY OFFICIAL BODIES UNLESS SPECIFICALLY STATED IN THE REPLY. ANONYMOUS COMMUNICATIONS AND QUERIES ON POSTAL CARDS WILL NOT BE NOTICED. EVERY LETTER MUST CONTAIN THE WRITER'S NAME AND ADDRESS, BUT THESE WILL BE OMITTED ON REQUEST.

CAUSES OF HYPOGLYCEMIA

To the Editor:—A married woman aged 27 has complained for the past two years of blurring of vision, dizzy spells, hunger, sense of anxiety and nervous irritability, sometimes accompanied by nausea prior to her meals. From twenty minutes to one hour after eating she complains of exhaustion, sleepiness, sometimes accompanied by heart palpitation, nausea and vomiting. On occasion she complains of one sided headaches always accompanied by nausea and vomiting and unexplained periods of nausea and vomiting and urinary frequency and urgency lasting for from a few hours to the entire day. She has had a dull aching pain in the left upper quadrant, not constant in character, radiating through to the back and up to the scapula for the past seven years. The patient gives a history of hay fever of seven years' duration with moderate relief with treatment. Physical examination is essentially negative except for transient cardiac arrhythmia with rapid thready pulse on one or two occasions following mental shock. She had no childhood diseases except diphtheria. When an adult, tonsillectomy was performed after a short period of rheumatic arthritis. The patient's blood pressure and temperature are normal. She has maintained her weight throughout this period and feels exceptionally well between these abnormal periods. Examination of the eyes was negative. The urine was normal and the Wassermann reaction negative. The blood count was normal. The chest x-ray examination gave normal results. The basal metabolism was -5 . The electrocardiogram was negative, taken one year prior to the cardiac arrhythmia. Gallbladder x-ray examination was negative. Gastrointestinal x-ray films were negative except for chronic appendicitis. The dextrose tolerance test was as follows:

	100 Gm. of Dextrose		25 Gm. of Dextrose
Before meals	80.6	85	95.2
One hour after.....	64.3	49.1	59.7
Two hours after.....	Not taken	99	78.1
Three hours after.....	70.7	99	88.9

Do you believe that this case of hyperinsulinism is due to neurosis, allergic phenomena, neoplasm of the pancreas or simple dysfunction? What suggestion can you offer as to diagnosis and treatment?

M.D., New York.

ANSWER:—It must be remembered that not all cases of hypoglycemia are due to hyperinsulinism. The differential diagnosis of hypoglycemia is fraught with difficulty. Apart from the pancreatic causes one must consider pituitary disease, adrenal disease and extensive liver disease in which there is failure to store glycogen. None of these seem to fit well into this picture but they should be carefully ruled out. Mild hypoglycemia also accompanies autonomic imbalance (vagotonia).

The case described shows numerous departures from the usual pattern. One of these departures is the dextrose tolerance curve. The typical "hyperinsulinism" curve usually starts from a fasting level of 60 mg. or less per hundred cubic centimeters. It rises during the first hour and then falls below the fasting level. The curve shown by this patient is known as a "reverse tolerance curve." That is to say, the curve falls immediately after the ingestion of dextrose and later returns to or near the fasting level. Less, if possible, is known about such a reaction than is known about "spontaneous hypoglycemia." Another departure from the usual pattern is the failure of food to relieve the symptoms. As a matter of fact, the ingestion of food seems to accentuate the symptoms. It would be helpful to know the blood sugar level in this patient during an attack. The effect of epinephrine in overcoming attacks should also be investigated.

If liver damage, pituitary disease and adrenal disease can all be eliminated in this case, one must still differentiate between pancreatic hypoglycemia and that due to neurogenic causes, and this is extremely difficult. Because of the atypical circumstances pointed out, the weight of evidence seems to favor a neurogenic cause. The hypothesis has been advanced that these neurogenic cases are due to an overreaction of the pancreas to the stimulation of dextrose. On this basis it has been suggested that frequent feedings low in carbohydrate and relatively high in protein would tend to lower this stimulation.

As a rule the diagnosis of pancreatic neoplasm cannot be confirmed except by exploratory operation. This would not seem justified in the present case until all other efforts had failed to solve the problem.

ACTION OF "STAINING" ANTISEPTICS

To the Editor:—Is there any difference in antiseptic value between two solutions of proved equal potency in vitro if one stains the tissues with which it comes in contact and the other does not? Does the staining substance enter into chemical combination with the tissue proteins? If it does, is there any greater danger of sensitization with the use of such a substance? Is a nonstaining solution absorbed to as great an extent as is a staining solution?

Seymour Schuback, M.D., New York.

ANSWER:—There are many sorts of stains used in the preparation of antiseptic solutions. Some of them have of themselves germicidal action but others have virtually none. They usually are added by manufacturers in order to delimit more clearly the area of skin being treated rather than to increase the bacteriostatic or bactericidal effect. It certainly cannot be assumed that addition of a stain necessarily increases the disinfectant power of any antiseptic solution.

Effective disinfection of tissues is primarily a problem (1) of employment of a potent agent and (2) of adequate contact between bactericide and bacteria. In standard in vitro tests, optimal and uniform conditions for such contact may obtain. But on skin and mucous membranes and in wounds contact with the bacteria present is an uncertain matter. Staining of tissues by no means assures that the solution has made contact with all the micro-organisms harbored there. Another factor, too often overlooked, is the degree to which tissues or their secretions combine with the chemical disinfectant so as to lessen its germicidal action. Thus on theoretical grounds, under certain conditions, it is conceivable that of "two solutions of proved equal potency in vitro" the one which stains the tissues might at the same time be "fixed" or otherwise neutralized in part by them, so as to become actually less effective as a disinfectant than the other solution.

Chemical "combinations" of stains with live tissues is a complex matter as yet incompletely understood. They involve "reactions" between substances whose chemical structures often are not fully known. Even more obscure is the chemistry of "sensitization." The answer to the question of whether there is greater danger of sensitization with the use of antiseptics which stain must be sought rather in the clinical experience of the profession. So far as known, no evidence has been accumulated to show that any degree of sensitization is attributable to staining properties of germicidal solutions. Untoward reactions are probably more often due to the chemical germicide itself, whether it discolors the tissues or not, rather than to any stain that may have been added to it. And it is doubtful whether staining of tissues is a dependable index of "chemical combination with the tissue proteins," absorption of the antiseptic or "danger of sensitization."

VITAMIN B₁ IN CARDIOVASCULAR AND GASTRO-INTESTINAL DISORDERS

To the Editor:—Has any clinical work been done to evaluate the use of vitamin B₁ in improving heart conditions, and vitamin B complex in functional stomach disorders? What is the value of these products in these specific conditions?

Irwin I. Lubowe, M.D., New York.

ANSWER:—Clinical studies of the effect of vitamin B₁ on cardiovascular disturbances in specific thiamine deficiency have been reported by Weiss and Wilkins, Jolliffe and Goodhart, Strauss and others. There is considerable evidence which indicates that the various members of the vitamin B complex have a definite function in gastrointestinal motility, and it is probable that a lack of either nicotinic acid or thiamine hydrochloride, or other unknown factors, is important in the development of certain functional digestive disorders. The literature concerning the relationship of the vitamin B complex to gastrointestinal malfunction has been reviewed by Chesley, Dunbar and Crandall and by Borsook and his co-workers.

HEMOGLOBIN ESTIMATIONS

To the Editor:—What is the most generally accepted normal figure for hemoglobin in the blood? Some systems figure 13.8 Gm. per hundred cubic centimeters of blood, others 14.5, some 16 and 17. This is confusing, especially since many physicians speak of it in terms of percentage and not in grams. J. Street Brewer, M.D., Roseboro, N. C.

ANSWER:—In making hemoglobin estimations the most important point is to determine the mean number of grams per hundred cubic centimeters on the basis of 5,000,000 red cells. Several such studies have been made in this country. Osgood found 14.29 Gm., Wintrobe 14.25 Gm. and Haden 15.38 Gm. It is possible that the amount varies in different sections of the United States. Since laboratory workers are not agreed on one figure for the normal amount of hemoglobin per hundred cubic centimeters of blood with a count of 5,000,000 red cells it is best to estimate the amount to be used for each laboratory. The standard is easily determined by estimating the hemoglobin in grams and counting the red cells in at least ten normal adults. The following example illustrates such a calculation:

Number	Red Cell Count per Cubic Millimeter (Millions)	Hemoglobin per 100 Cc. of Blood (Grams)
1	5.02	15.5
2	4.00	12.6
3	4.65	14.9
4	5.50	16.8
5	4.78	15.0
6	4.57	14.2
7	4.25	13.5
8	5.31	16.5
9	5.80	16.9
10	4.92	15.1
Mean	4.88	15.1

The hemoglobin in grams per hundred cubic centimeters of blood calculated for a count of 5,000,000 red cells is $\frac{5.00 \times 15.1}{4.88} = 15.4$ Gm.

This figure will give a color index within normal limits in normal persons for the laboratory in which it is determined.

DOES CORAL GROW IN HUMAN TISSUE?

To the Editor:—The beaches in the vicinity of Honolulu are filled with coral mixed with sand. This coral is thrown up by the waves, and naturally a considerable amount gets into the ears of bathers. Most persons do not notice the presence of the coral in the ears for periods ranging from one week to several weeks and the first complaint is pain in the ear and a whitish discharge. When the ear is examined, small coral growths are noted. The canal itself is not particularly inflamed but is swollen and macerated. I have seen growths of coral formation about the size of half a dime (5 mm.) and branching in coral formation along the canal. It is my impression that this coral grows in the canal, for after apparent cure from treatments given the condition recurs without the patient having been in bathing again. I have found that the milder forms of treatment such as warm boric acid irrigations followed by phenol and glycerin are of more benefit than the more aggressive treatments. In this connection also I have heard of several cases on the islands of coral growing in the tissues of persons who have had coral lacerations and abrasions after the wounds have apparently healed. I can find nothing in the standard books on this subject but am informed that this does occur and that, if the coral gets into the bony structure, quite a serious condition results. Can you give me any information regarding such a possibility? I have also been informed on numerous occasions that one should never use tincture of iodine on coral inflicted wounds. The reason is given that the animal life producing the skeletal coral grow or feed on the iodine content of the sea water and therefore iodine enhances the growth of the animal rather than inhibits it. Is there any truth in this assertion and if so what would be the accepted form of treatment of coral wounds? M.D., Pearl Harbor, T. H.

This inquiry was referred to Dr. Nils P. Larsen, medical director of the Queen's Hospital, Honolulu, who replied as follows:

ANSWER:—This old Hawaiian superstition is believed by certain natives and is often repeated but it lacks foundation in fact. In my eighteen years at the Queen's Hospital we have performed more than 300 autopsies a year but have failed to see anything of this nature. As a hobby I have taken up diving and underwater photography and have been down on the coral beds in every part of this island and three other islands. I don't believe there is a variety of coral that grows in Hawaiian waters on which I have not been cut and scratched. In one accident I fell into one of the big coral trees in Kaneohe Bay and had cuts the entire length of my body from my ankles to my forehead. In that particular bay every coral cut raises a deep red welt. This condition, however, clears in twenty-four hours. Considering the extreme differences of metabolism, growth and type of animal between coral and man, the statements recall that of the young botanist who thought dandelions could be grafted on apple trees.

The reason for the old Hawaiian superstition about coral growing in a patient I believe comes from the natives seeing sequestrums come from cases of osteomyelitis. Since nearly all patients here with osteomyelitis usually get their cuts in connection with the sea, and since in every part of the sea there is coral, when they saw an irregular piece of bone escape from a wound and the leg was greatly swollen it would be easy to think that it was actually coral growing in the wound.

RECURRENT CANCER OR SURGICAL ELEPHANTIASIS

To the Editor:—A woman eight years ago had a radical operation for cancer of both breasts. About six weeks ago her right arm, shoulder and right side of the chest became swollen. Careful examination and roentgenograms showed no malignant growth and the diagnosis was lymphangiectasis. There has been no improvement during this period and the arm is uncomfortable at all times and especially when an attempt is made to use it. Even the hand becomes swollen and bluish. Can you suggest any treatment? M.D., California.

ANSWER:—The question arises as to whether the edema of the arm in the case described is due to recurrent disease along the axillary vein or whether the condition is an example of elephantiasis chirurgica. The negative clinical and x-ray observations constitute evidence against but do not totally exclude recurrent disease as a causative factor. If recurrent disease along the axillary vein is demonstrated or suspected, radiation therapy is indicated and offers some hope of relief. The treatment of elephantiasis chirurgica presents great difficulties and on the whole has been unsatisfactory. Handley recommends lymphangioplasty in certain cases. It has been suggested recently that small doses of x-rays over the arm have given improvement, but these observations have not yet been confirmed. Application of heat gives only occasional and temporary relief. Elevation of the arm is helpful.

MECHANICAL AND MALARIAL FEVER THERAPY
IN SYPHILIS

To the Editor:—Do the diathermy heat treatments give better results than malaria fever treatments in cases in which the spinal Wassermann reaction is positive? Is it advisable to use fever treatments in cases in which the spinal Wassermann reaction is negative but the blood Wassermann reaction remains positive despite antisyphilitic treatment?

Arthur Leistyna, M.D., Ilion, N. Y.

ANSWER:—A recent survey by a subcommittee of the Cooperative Clinical Group of the value of fever therapy administered by malaria and by mechanical means will appear in print shortly. The study showed that the results from the machine therapy and from malaria were practically the same in a group of patients with dementia paralytica. Each method of treatment has certain advantages over the other, which, however, tend to offset each other so that the final results are much the same.

The use of fever therapy is indicated for patients with neurosyphilis who present clinical signs of nervous system involvement or who have a positive spinal fluid test. The patient with clinical neurosyphilis, when the signs are suggestive of dementia paralytica or when the results of chemotherapy are not satisfactory, should be given the advantage of fever therapy immediately. If the patient has no clinical signs of neurosyphilis but has a positive spinal fluid test (especially if it has parietic characteristics) a course of fever therapy may be given when two sources of chemotherapy have failed to improve the spinal fluid reaction. Fever therapy is not indicated for patients who have latent syphilis with a persistently positive Wassermann or flocculation reaction of the blood.

EOSINOPHILIA WITH GASTROINTESTINAL SYMPTOMS

To the Editor:—The answer to the question "Eosinophilia with Gastrointestinal Symptoms" (The Journal, September 21, p. 1041) reasonably suggests the possibility of an allergic etiology. The existence of an allergic mechanism—probably of food sensitivity—is quite likely in this particular instance. I have studied a number of allergic children with gastrointestinal symptoms due to food allergy (Roentgen Studies of Children with Alimentary Disturbances Due to Food Allergy, *Am. J. Dis. Child.* 5:4:1239 [Dec.] 1937). Gastric retention of varying degrees in association with pylorospasm were characteristic. These observations parallel those of the inquirer in the query in question. The recurrent (periodic) nature of the patient's attacks, consisting of abdominal pain and protracted vomiting, again suggest a possible food sensitivity. Dr. Kenneth G. Jennings and I are publishing observations made on a group of children suffering from recurrent attacks of vomiting abdominal pain which would seem to be similar to the attacks of this patient (Recurrent Vomiting in Children: The Factor of Food Hypersensitivity, *J. Pediatr.*, to be published). A more careful inquiry into the patient's diet with particular emphasis on possible food sensitivities might be revealing.

Joseph H. Fries, M.D., Brooklyn.

Medical Examinations and Licensure

COMING EXAMINATIONS

NATIONAL BOARD OF MEDICAL EXAMINERS EXAMINING BOARDS IN SPECIALTIES

Examinations of the National Board of Medical Examiners and Examining Boards in Specialties were published in THE JOURNAL, October 19, page 1394.

BOARDS OF MEDICAL EXAMINERS

ALABAMA: Montgomery, June 17-19. Sec., Dr. J. N. Baker, 519 Dexter Ave., Montgomery.

ARKANSAS: * *Regular*. Little Rock, Nov. 7-8. Sec., Dr. D. L. Owens, Harrison. *Eclectic*. Little Rock, Nov. 7. Sec., Dr. Clarence H. Young, 1415 Main St., Little Rock.

CALIFORNIA: *Oral examination* (required when reciprocity application is based on a state certificate or license issued ten or more years before filing application in California), Los Angeles, Dec. 11. Sec., Dr. Charles B. Pinkham, 1020 N St., Sacramento.

CONNECTICUT: * *Written*. Hartford, Nov. 12-13. *Endorsement*. Hartford, Nov. 26. Sec., Dr. Thomas P. Murdock, 147 W. Main St., Meriden. *Homeopathic*. Derby, Nov. 12-13. Sec., Dr. Joseph H. Evans, 1488 Chapel St., New Haven.

DELAWARE: July 8-10. Sec., Medical Council of Delaware, Dr. Joseph S. McDaniel, 229 S. State St., Dover.

DISTRICT OF COLUMBIA: * Washington, Nov. 11-12. Sec., Commission on Licensure, Dr. George C. Ruhland, 203 District Bldg., Washington.

FLORIDA: * Tampa, Nov. 18-19. Sec., Dr. W. M. Rowlett, Box 786, Tampa.

HAWAII: Honolulu, Jan. 8-11. Sec., Dr. James A. Morgan, 48 Young Building, Honolulu.

INDIANA: Indianapolis, June 17-19. Sec., Board of Medical Registration and Examination, Dr. J. W. Bowers, Citizens Trust Bldg., Fort Wayne.

IOWA: Des Moines, Dec. 9-11. Dir., Division of Licensure and Registration, Mr. H. W. Grefe, Capitol Bldg., Des Moines.

KANSAS: Topeka, Dec. 10-11. Sec., Dr. J. F. Hassig, 905 N. Seventh St., Kansas City.

KENTUCKY: Louisville, Dec. 3-5. Sec., State Board of Health, Dr. A. T. McCormack, 620 Third St., Louisville.

MAINE: Portland, Nov. 12-13. Sec., Board of Registration of Medicine, Dr. Adam P. Leighton, 192 State St., Portland.

MARYLAND: *Regular*. Baltimore, Dec. 10-13. Sec., Dr. John T. O'Mara, 1215 Cathedral St., Baltimore. *Homeopathic*. Baltimore, Dec. 10-11. Sec., Dr. John A. Evans, 612 W. 40th St., Baltimore.

MASSACHUSETTS: Boston, Nov. 12-14. Sec., Board of Registration in Medicine, Dr. Stephen Rushmore, 413-F State House, Boston.

MISSISSIPPI: *Reciprocity*. Jackson, December. Asst. Sec., State Board of Health, Dr. R. N. Whitfield, Jackson.

MISSOURI: Kansas City, Oct. 29-31. Sec., State Board of Health, Dr. Harry F. Parker, State Capitol Bldg., Jefferson City.

MONTANA: *Reciprocity*. Helena, March 31. *Written*. Helena, April 1. Sec., Dr. S. A. Cooney, 216 Power Block, Helena.

NEBRASKA: * Lincoln, Nov. 7-9. Dir., Bureau of Examining Boards, Mrs. Clark Perkins, 1009 State Capitol Bldg., Lincoln.

NEVADA: *Reciprocity* with oral examination, Nov. 4. Sec., Dr. Fred M. Anderson, 215 N. Carson St., Carson City.

NEW HAMPSHIRE: Concord, March 13-14. Sec., Board of Registration in Medicine, Dr. T. P. Burroughs, State House, Concord.

NEW YORK: Albany, Buffalo, New York and Syracuse, Jan. 27-30. Chief, Bureau of Professional Examinations, Mr. Herbert J. Hamilton, State Education Department, 315 Education Bldg., Albany.

NORTH CAROLINA: *Reciprocity*. Durham, Dec. 10. Sec., Dr. W. D. James, Hamlet.

NORTH DAKOTA: Grand Forks, Jan. 7-10. Sec., Dr. G. M. Williamson, 4½ S. Third St., Grand Forks.

OHIO: Columbus, Dec. 9-12. Sec., Dr. H. M. Platter, 21 W. Broad St., Columbus.

OKLAHOMA: * Oklahoma City, Dec. 11. Sec., Dr. James D. Osborn Jr., Frederick.

OREGON: * *Reciprocity*. Portland, October. *Written*. Portland, Jan. 14-16. Exec. Sec., Miss Lorraine M. Conlee, 608 Failing Bldg., Portland.

PENNSYLVANIA: Philadelphia, January. Acting Sec., Bureau of Professional Licensing, Miss Marguerite G. Steiner, 358 Education Bldg., Harrisburg.

SOUTH CAROLINA: Columbia, Nov. 12. Sec., Dr. A. Earle Booser, 505 Saluda Ave., Columbia.

SOUTH DAKOTA: * Pierre, Jan. 21-22. Dir., Medical Licensure, Dr. J. F. D. Cook, Pierre.

TEXAS: Austin, Nov. 25-27. Sec., Dr. T. J. Crowe, 918-920 Mercantile Bldg., Dallas.

VERMONT: Burlington, Feb. 11. Sec., Dr. W. Scott Nay, Underhill.

VIRGINIA: Richmond, Dec. 4-6. Sec., Dr. J. W. Preston, 30½ Franklin Rd., Roanoke.

WEST VIRGINIA: Morgantown, Oct. 31-Nov. 2. Sec., Public Health Council, Dr. Arthur E. McClue, State Capitol, Charleston.

WISCONSIN: * Madison, Jan. 14-17. Sec., Dr. H. W. Shutter, 425 E. Wisconsin Ave., Milwaukee.

* Basic Science Certificate required.

BOARDS OF EXAMINERS IN THE BASIC SCIENCES

MICHIGAN: Ann Arbor, Detroit and East Lansing, Feb. 14-15. Sec., Miss Flora E. Dube, East Lansing.

OKLAHOMA: Oklahoma City, Nov. 18. Sec. of State, Hon. C. C. Childress, State Capitol, Oklahoma City.

RHODE ISLAND: Providence, Nov. 20. Acting Chief, Division of Examiners, Mr. E. Clyde Thomas, 366 State Office Bldg., Providence.

SOUTH DAKOTA: *Examination*. Yankton, Dec. 6-7. *Endorsement*. Dec. 21. Sec., Dr. Gregg M. Evans, Yankton.

WISCONSIN: Milwaukee, Dec. 7. Sec., Prof. Robert N. Bauer, 3414 W. Wisconsin Ave., Milwaukee.

Arizona July Report

Dr. J. H. Patterson, secretary, Arizona State Board of Medical Examiners, reports the written examination for medical licensure held at Phoenix, July 2-3, 1940. The examination covered ten subjects and included 100 questions. An average of 75 per cent was required to pass. Four candidates were examined, three of whom passed and one failed. The following schools were represented:

School	PASSED	Year Grad.	Number Passed
Tulane University of Louisiana School of Medicine.....	(1936)		1
University of Nebraska College of Medicine.....	(1939)		1
University of Tennessee College of Medicine.....	(1939)		1
School	FAILED	Year Grad.	Number Failed
St. Louis University School of Medicine.....	(1938)		1

Ohio June Report

Dr. H. M. Platter, secretary, Ohio State Medical Board, reports the oral, practical and written examination for medical licensure held at Columbus, June 3-6, 1940. The examination covered eleven subjects and included eighty questions. An average of 75 per cent was required to pass. Two hundred and sixty candidates were examined, 253 of whom passed and seven failed. The following schools were represented:

School	PASSED	Year Grad.	Per Cent
University of California Medical School.....	(1940)		81.8

Book Notices

The Louse: An Account of the Lice Which Infest Man, Their Medical Importance and Control. By Patrick A. Buxton, M.A., M.R.C.S., L.R.C.P., Director, Department of Medical Entomology, London School of Hygiene and Tropical Medicine, London. Cloth. Price, \$3. Pp. 115, with 28 illustrations. Baltimore: William Wood & Company, 1940.

The existence of war conditions makes more important than previously complete information regarding the dissemination of lice of the body, the head and the pubis, and also of methods of prevention and control. The little book by Dr. Buxton is probably the most complete available and is certainly an authoritative contribution. It covers every aspect of the subject and in the appendix provides details of the technic to be used in research as well as a complete bibliography and a good index.

Cancer in Childhood and a Discussion of Certain Benign Tumors. Edited by Harold W. Dargeon, M.D., F.A.A.P., Attending Pediatrician, Memorial Hospital for Cancer and Allied Diseases, New York. Cloth. Price, \$3. Pp. 114, with 51 illustrations. St. Louis: C. V. Mosby Company, 1940.

This is a symposium on neoplastic diseases of children. It is a collection of papers which have been previously published almost entirely in the *Journal of Pediatrics* by various members of the staff of the Memorial Hospital and represents the experiences at this hospital for cancer and allied diseases. The book is introduced by two chapters which relate to the general aspect of childhood cancer and serve to unify an otherwise disjointed array of material. The first chapter is written by James Ewing and includes a review of those features of cancer peculiar to the young together with a concise survey of various related subjects. The chapters on the whole are brief and include, in addition to the first two, sections on tumors of bone, the leukemias and allied diseases, genito-urinary cancer, gynecologic cancer, cancer of the head and neck, and blood and lymph vessel tumors. Lack of balance, frequently encountered in symposiums, and cursory treatment of the subject matter is observed in some of the sections. For example, the chapter on bone tumors, which stresses the importance of x-ray examinations, contains no reproductions of roentgenograms although more than fifty illustrations are included in the book. The chapter on tumor of the soft somatic structures, however, deserves commendation for its careful arrangement and lucid presentation. Of special interest to the pediatrician will be the tables presenting mortality statistics of the U. S. Department of Commerce and of the Bureau of Records of New York City. These show definitely that cancer is one of the important diseases of children. Additional data contained in the book lend further emphasis to such a conclusion. Although the book cannot be considered a complete treatise on cancer in children, considerable valuable information is presented.

The Hypothalamus and Central Levels of Autonomic Function. Proceedings of the Association, December 20 and 21, 1939, New York. Editorial Board: John F. Fulton, M.D., Chairman, S. Walter Ranson, M.D., and Angus M. Franz, M.D. Research Publications, Association for Research in Nervous and Mental Disease, Volume XX. Cloth. Price, \$10. Pp. 980, with 319 illustrations. Baltimore: Williams & Wilkins Company, 1940.

In this volume are collected papers reported before the Association for Research in Nervous and Mental Disease. The subject of the hypothalamus is considered under the three headings anatomy, physiology and clinical. In the first part an anatomic atlas is included which should be invaluable for all workers in the field. The first and second portions are complete and summarize all that is really known on the subject. The third part is the weakest and cannot be compared favorably with the remainder of the book. A concise survey of the clinical syndromes cannot be obtained from this work and must be searched for elsewhere. The bibliography is extensive and satisfactory. There is an excellent index which makes the book an adequate tool for the investigator. The editorial board is to be congratulated for a brilliant collection of summarizing papers from which subsequent investigators may take off for further advances on the subject.

Traité de l'immunité dans les maladies infectieuses. Par le Dr Jules Bordet, Directeur de l'Institut Pasteur de Bruxelles. Second edition. Paper. Price, \$3.90. Pp. 879. Paris: Masson & Cie, 1939.

The first edition of this valuable textbook on immunity appeared about 1920. Besides being brought entirely down to date, the volume has acquired 160 additional pages. The reference publications cover both those of the Old and those of the New World, attesting the author's broad acquaintance with the literature. The introduction points out that life is maintained by an equilibrium continually menaced in which correlation of functions is rarely perfect but defects are corrected by various phenomena of adaptation. Immunity in its various aspects is analyzed and its importance in the progress of science pointed out.

The book is divided into four appropriate parts: The first considers generalities such as infection and the factors of virulence, taking up variously the nature and properties of microbial poisons, endotoxins, anatoxins, vegetable toxins, animal poisons and the mechanism of intoxication, followed by variations of virulence, variations, R and S inequalities, variabilities of metabolism and the origin of virulence; then the circumstances favoring infection; the penetration of microbes and extension of infection covering contagiousness, portal of entry, penetration of toxins, organotropy and cytotoxicity, incubation, latent microbialism and inapparent infections; included next are the causes of death, specific and nonspecific; then natural and acquired immunity are appropriately considered with age, species, heredity and individual chemical differences as well as the part played by inflammation and phagocytoses, the various phases of vaccination in the mechanism of acquired immunity, with the significance of passive and active immunity, detailed to the role of the placenta and milk. Allergy, anaphylaxis and hypersensitiveness are detailed under incomplete acquired immunity; finally, the first chapter considers protein therapy and pyretotherapy, with a chapter on the general significance of the phenomenon of immunity. Part 2 dwells on cellular immunity with phagocytoses and resorption; phagocytosis, inflammation, and immunity; the circulatory system and inflammation; the adjuvant factors such as opsonins and exudates are considered appropriately. Part 3 takes into consideration the humoral factors of immunity such as antitoxins and antiferments; the agglutinant, bacteriolytic, hemolytic, precipitant and cytotoxic factors are given full elucidation; antitryptic actions, lysozyme, autolysis, complement fixation, including the serodiagnosis of syphilis, flocculation reactions, haptens and artificial antigens as well as the chemical nature of antibodies are presented; in this part also are given the various theories on the mode of union of antibodies and antigens as well as their specificity; finally, blood groupings and their relations in man and animals are detailed. The fourth main division of the book deals with the exact parts played by immunity in specific diseases and immunity in malignant tumors; finally anaphylaxis and allergy are analyzed into their various phenomena—antianaphylaxis, anaphylatoxins, the role of anaphylaxis in pathology, the character of allergy, the hemorrhagic reactions (Sanarelli, Schwartzman), and finally the significance of allergy and immunity especially in tuberculosis closes this extensive work covering one of the most intricate phases of modern science.

In spite of the voluminous character of this valuable textbook, unfortunately it will suffer the shortcomings of any work in a field undergoing such rapid scientific advances as those occurring in the field of immunology. This will probably be the criticism offered by the investigator; but for a ready reference or a student's textbook in immunology it should fill an important place especially for the scientific and medical scholar able to read French fluently. Illustrations and tables are noteworthy for their absence, but in this field the lack is not felt as much as would be the case in other closely related fields of medicine.

The publisher has done a creditable job on a good grade of paper and at a modest price. The paper cover need be no drawback to those who handle their books carefully and who are primarily interested in the subject matter presented. The volume can be recommended to all interested in the broad subject of immunity in its various phases and not requiring technics and technical details.

Pneumokoktypernes forekomst i Danmark. Af Børge Vammen. [Occurrence of Pneumococcal Types in Denmark.] Denne Afhandling er af det lægevidenskabelige Fakultet antaget til offentlig at forsvares for den medicinske Doktorgrad, København, 1940. [With an English Summary.] Paper. Price, 8 Danish kroner. Pp. 104. Copenhagen: Ejnar Munksgaard, 1940.

Dr. Vammen has contributed, from Denmark, an excellent study on the type distribution in the pneumococcal pneumonias. The occurrence of various pneumococcus types as reported by investigators in Denmark, England and elsewhere and in America, where the intensive study of this subject originated, are compared in tables. The distribution of the types is similar in various places excepting for a strikingly greater incidence of type II in Denmark and England than in New York and Boston. There is an English translation of the excellent summary and numerous comprehensive tables, so that this book will be of value to workers unfamiliar with the Danish language. Vammen has added several additional new types to those of Cooper. They have been segregated from the x group or by more refined differentiation from some of the older types, notably IX and X. Vammen pleads for the establishment of a central international source for the preservation and distribution of pneumococcus strains and diagnostic serums. Under present conditions of world strife, this would be difficult. However, the William Hallock Park Laboratory of the New York City Department of Health has distributed cultures and typing serums since Georgia Cooper first described her types. The types are preserved by the American Type Culture Association; there will be unfortunate confusion if new numbers are assigned by each worker without consultation with some central responsible office. Vammen observes that "Repeated examinations of the nursing staff of a ward with many pneumonia patients showed that only 1.3 per cent had the same types as those found in the pneumonia patients of the ward. This low frequency, as compared with the frequency in family contacts, indicates that other circumstances than contact also play a part in the genesis of the carrier state." However, other circumstances need not be brought in until the closeness and continuity of contact and the use of utensils which occurs in family life are considered. This monograph is an exemplar of fine Scandinavian medicine and of the growing influence of American research. It appeared before the recent violation of Denmark and it is hoped that the western progress of Nazism will not spell the twilight of intellectual effort in the northern countries.

The Enamel of Human Teeth: An Inquiry into the Formation of Normal and Hypoplastic Enamel Matrix and Its Calcification. By Moses Diamond and Joseph P. Weinmann. From the Division of Oral Anatomy, School of Dental and Oral Surgery, Columbia University. Paper. Price, \$1.50. Pp. 105, with 52 illustrations. New York: Columbia University Press, 1940.

The authors reject the generally accepted hypothesis of Retzius that human tooth enamel is formed in layers from within outward and that the organic matrix of each layer is calcified progressively as developed. According to them the organic matrix is formed in layers much as claimed by Retzius, but it is impregnated as it is produced with mineral salts in a colloidal state. The consistency of this matrix is not as soft as that of cheese or soft enough to be cut with the finger nail as described by Ebner and Beust but much firmer. Although the amount of contained mineral salts may progressively increase as the matrix grows older, there is no calcification until the full thickness of the matrix is fully formed and the enamel organ has begun to atrophy and undergo reduction. Then and then only does the relatively firm matrix with its content of colloidal minerals change into the mature hard, stonelike enamel. The term calcification according to the authors should be limited strictly to this last change. Hypoplasia of tooth enamel, they believe, is due to disturbances in the production of enamel matrix and not to disturbances of calcification. Furthermore, hypoplasia is limited in its origin to the last four prenatal months and the first year after birth. The principal contention of the authors seems to be adequately supported by strong evidence from their own and other material. Confirmation of some of the details is dependent on further examination by other methods, chiefly chemical, than those used. Many of the conclusions with respect to hypoplasia are to be doubted because they are based on too

little evidence and because too little attention has been given to the effects of injuries on undifferentiated and fully differentiated cells and the consequent differences in the results. The type is unnecessarily large and the illustrations unduly generous in size; the printing, paper, cuts and workmanship are of high quality. There is an adequate bibliography.

Fractures and Other Bone and Joint Injuries. By R. Watson-Jones, B.Sc., M.Ch.Orth., F.R.C.S., Consulting Orthopaedic Surgeon, Royal Lancaster Infirmary, Lancaster. Cloth. Price, \$13.50. Pp. 723, with 1,019 illustrations. Baltimore: William Wood & Company, 1940.

The scope of this book goes far beyond the usual territory covered in books on fractures and dislocations. It includes all traumatic situations, including sprains and muscular injuries, and its principal virtue is the extreme thoroughness with which this field is covered in all details. The general principles which are announced at the beginning of the book are extremely sound and splendidly presented. Of particular value are the chapters on constitutional conditions in which trauma is the contributory factor. There is also an excellent chapter on vascular necrosis or aseptic necrosis in relation to trauma and an equally good one on vascular injuries complicating fractures. The chapter on nerve complications contains not only the treatment but also diagnosis and differentiation attendant on nerve injuries. One of the most important contributions is the presentation of the principles of fracture reduction, manipulative, standard of the reduction, plaster technic, traction, fixed and balanced, and transfixion technic. Everything is described in minute detail. The second part of the book deals with pathologic fractures, and here particularly the osteo-arthropathies and osteomalacias are of interest. Birth fractures are described in a separate chapter. In the third part the regional description of fractures is presented. Particularly attractive is the chapter on injuries of the trunk and head, and on the fractures and subluxations of the vertebrae. It is followed by an equally excellent chapter devoted to low back pain and sciatica with a splendid presentation of diagnosis and treatment. Of great value also are the chapters of the injuries of the shoulder, the section on peri-arthritis and the injuries and fractures of the elbow, particularly the supracondylar fractures. Fractures of the upper end of the femur and neck of the femur are given an equally thorough consideration. There are also the injuries of the knee and the ankle in special chapters. It would be going too far to point out all the excellent features of the book, which repeat themselves in every succeeding chapter. Presentation is superb, the illustrations are excellent, the material produced is rich, the roentgenograms are of the first quality. All in all, a most excellent book of almost overwhelming thoroughness, practical presentation, and most attractively and artistically edited.

The Diagnosis and Treatment of Pulmonary Tuberculosis. By John B. Hawes 2d, M.D., and Moses J. Stone, M.D., Assistant Professor of Medicine, Boston University School of Medicine, Boston. With a foreword by Richard C. Cabot, M.D. Second edition revised by Dr. Moses J. Stone. Cloth. Price, \$2.75. Pp. 260, with 75 illustrations. Philadelphia: Lea & Febiger, 1940.

This book was apparently designed for medical students and general practitioners. Adhering strictly to the subject and considering the authors' avowed purpose of presenting "a brief concise textbook," it is obvious that the book contains some superfluous material and in certain chapters there is a crying need for a clearer statement of fundamental facts, a more detailed description of symptoms and signs and methods of procedure. The reader often comes to the end of a sentence longing for one or two additional words or he rounds out a paragraph wishing for another sentence for clarification. The medical student and the average doctor wanting in knowledge and experience to spread between the lines will close certain chapters with a feeling of confusion and disappointment. The chapter on roentgen ray diagnosis may be cited as an example. In this chapter considerable space is devoted to a discussion of pathologic types of pulmonary tuberculosis without giving a detailed description of the roentgen appearances in the respective types. The illustrations are good but the legends are not fully descriptive and they are not clearly identified with the text, which also is wanting in the matter of explicit interpretation. The same may be said of the illustrations in other chapters. On

the whole, this little volume contains much valuable material and many practical features which are not to be found in many of the more comprehensive textbooks. The historical approach is good and should help to arouse interest. The chapter on history taking is logically presented with a sound psychologic approach. The chapter on sanatorium treatment is good but it does not sufficiently stress the importance of the education of the patient and adequate follow-up after the sanatorium treatment is completed. The comparison of home and sanatorium treatment is well handled. Collapse therapy is brought down to the present with a brief but sound discussion. The authors are to be commended for their decided stand against preventoriums and summer camps "for individuals who have primary tuberculosis," also because of their conservative attitude toward climate and other controversial procedures, such as extrapleural pneumothorax and oleothorax.

Minor Surgery. By Frederick Christopher, S.B., M.D., F.A.C.S., Associate Professor of Surgery at the Northwestern University Medical School, Chicago. With a foreword by Allen B. Kanavel, M.D., F.A.C.S. Fourth edition. Cloth. Price, \$10. Pp. 990, with 639 illustrations. Philadelphia & London: W. B. Saunders Company, 1940.

That this is the fourth edition in eleven years attests the popularity of this book and the immensely practical task it fulfills. The collection of a tremendous amount of authoritative data freely fortified by numerous and recent references is, in itself, a considerable accomplishment. The large amount of material included occasionally permits a slight element of confusion to creep in. Quotations from a number of authorities lend credence to a point of view without justifying its inclusion in a book of this nature. A good portion of the book has been prepared with the surgical intern and resident in mind.

It is interesting to note that the injection technic for inguinal hernia has been properly omitted despite its reported good results in the hands of a limited number of experts. Future editions will no doubt contain even less controversial matter as the fields of major and minor surgery grow more distinct. As the author states, no one knows exactly what is minor surgery; but it covers a myriad of conditions of lesser debilitating character. First aid treatment, also included in this book, is often preliminary treatment of injuries of serious nature. The definition of minor surgery as evaluated in this book can be summarized as major procedures on minor diseases and minor procedures on major diseases.

The author has assembled this vast array of material with considerable circumspection, cohesion and clarity. The value of the book in traumatic surgery cannot be denied in an age of increasing mechanical accidents. The methods of handling injuries to the extremities, fractures of the smaller bones, splinting and first aid treatment are well described. There are numerous illustrations obtained from the publications of competent authorities. This volume can be recommended to every surgical intern, resident and practicing physician.

Der gehemmte Mensch: Grundlagen einer Desmologie als Beitrag zur Tiefenpsychologie. Von Dr. med. Harald Schultz-Hencke. Paper. Price, 16.80 marks. Pp. 323. Leipzig: Georg Thieme, 1940.

This book is a typical outgrowth of German "science" of today, evidently written to prove to the political overseers of medical science in that country that the author is no longer to be regarded as contaminated by the "Jewish science" psychoanalysis with which he was formerly identified. Compilations from unquoted sources and an arbitrary choice of facts to fit a preconceived system are its main characteristics. Many of the discoveries of Freud are accepted as being matters of common knowledge, but Freud is never given any credit; he is quoted only when the author disagrees with him, which is quite often, or wishes to reproach him for having introduced confusing terms and erroneous conceptions. The author himself introduces a few new terms, such as "captive" and "retentive" tendencies, which he thinks clear matters up immensely. He denies the existence of infantile sexuality, although he furtively exploits many of the deductions drawn from Freud's observations of these phenomena. Not only Freud but other authorities are ignored in favor of the presumption that the author is the originator of his confused collection of psychiatric observations and theories. The book is not worth reading except as an illustration of how state politics can ruin medical science.

A Handbook for Dissectors. By J. C. Bolleau Grant, Professor of Anatomy, University of Toronto, Toronto, and H. A. Cates, Associate Professor of Anatomy, University of Toronto. Being a Companion to "A Method of Anatomy" by J. C. Bolleau Grant. Third edition. Fabrikoid. Price, \$2.50. Pp. 239, with 9 illustrations. Baltimore: William Wood & Company, 1940.

This little book is intended for use with Grant's "A Method of Anatomy." Experience has evidently shown the need of directions for dissection additional to those contained in the larger book, hence this supplementary one. The directions are precise and clear. Endeavor has been made to help the student leave out something: the more important structures are printed in heavy type. This book and "The Method" together constitute an excellent guide to the first (and usually only) dissection made by medical students. Since the outlook of both books is toward clinical work in surgery and medicine, dissection under their guidance provides a good practical anatomic basis for further medical work. But students who are interested in anatomy rather from the biologic side, who seek to understand the principles of structure, its evolution, development and general plan, will go on to a study of the larger textbooks, perhaps with further dissection. Since this book is tied so closely to "The Method" by constant reference to its pages and its illustrations and is thus inseparable from it, one wonders if in future editions of "The Method" this little book might not be incorporated in it.

The Diabetic A B C: A Practical Book for Patients and Nurses. By R. D. Lawrence, M.A., M.D., F.R.C.P., Physician in Charge Diabetic Department, King's College Hospital, London. Seventh edition. Boards. Price, 3s. 6d. Pp. 64. London: H. K. Lewis & Co., Ltd., 1940.

The seventh edition of Dr. Lawrence's pasteboard covered manual for the use of patients is proof of its usefulness. It is short, concise, goes straight to the point and all concerned in the treatment of diabetes will approve of its orthodox character. The author's line ration scheme of prescribing has won more adherents in England than in this country. One line represents food containing the equivalent of 10 Gm. of carbohydrate, 7.5 Gm. of protein and 9 Gm. of fat. Dr. Lawrence believes in weighing diets, at least at the beginning of treatment, and at intervals thereafter. Of especial interest now is a part of the second paragraph of the preface: "So far the war has not brought any special hardships for diabetics, but I wish to mention two points about which I have received hundreds of enquiries. First, vitaminised margarine is just as good as butter for the nutrition of diabetics. And second, diabetics can obtain an extra meat ration in exchange for sugar by applying to their local food office."

As the Twig Is Bent. By Leslie B. Hohman, M.D., Associate in Psychiatry, Johns Hopkins Medical School, Baltimore. Cloth. Price, \$2.50. Pp. 291. New York: Macmillan Company, 1940.

This is a collection of twenty-six essays on child guidance written for parents in an unusually readable literary style by a psychiatrist. The book will be enjoyed by parents because of the many well portrayed examples of human problems and the breeziness with which the author demonstrates their possible solutions. "Common sense" seems to be the solution for all psychologic problems, which thus evaporate like mist before the morning sun. The author is not a child psychiatrist and his naïveté which pervades the book and gives it such an optimistic note is ample evidence of his lack of experience in dealing with the "bent twig." Rules, precepts and logic, but not one sentence indicating a basic understanding of the child's emotional life.

Bibliografiya Russkoy radiologii i rentgenologii za 1896-1938 gg. [By] A. E. Molotkov. Pod redaktsiyey I. S. predslavlyem M. I. Nemenova. Vypusk 1. Radiy i radioaktivnye veshchestva rykhodit k 40-letiyu so dnya otkrytiya radiya (1898-1938). Bibliographie de radiologie et de roentgenologie russe pour la période 1896 à 1938. Fascicule 1. Radium et substances radioactives paru à l'occasion du quarantenaire de la découverte du radium (1898-1938). Paper. Price, 4 rubles. Pp. 55. Leningrad: Izdanie Gosudarstvennogo Rentgenologicheskogo, Radiologicheskogo i Rakovogo Instituta i Vsesoyuznogo Instituta Eksperimental'noy Meditsiny imeni A. M. Gorkogo, 1938.

The aim of the publishers is to collect all the Russian literature on the subject of roentgen and radium radiation therapy. The present volume is devoted to the cataloguing of all the available literature in Russian on the subject of radium from 1896 to 1938. Some 700 titles are listed.

Current Medical Literature

AMERICAN

The Association library lends periodicals to members of the Association and to individual subscribers in continental United States and Canada for a period of three days. Three journals may be borrowed at a time. Periodicals are available from 1930 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 18 cents if three periodicals are requested). Periodicals published by the American Medical Association are not available for lending but can be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

American Journal of Clinical Pathology, Baltimore

10:511-592 (Aug.) 1940

- Histopathology of Defective Scar of High Cesarean Section and Mechanism of Subsequent Rupture of Uterus. N. W. Elton, Buffalo.—p. 511.
- Rapid Flocculation Test for Syphilis Adapted to Cerebrospinal Fluid. W. F. Lorenz, Madison, Wis.—p. 527.
- Pathologic Classification of Diseases of Myocardium. G. E. Brown Jr. and H. F. Hunt, Danville, Pa.—p. 540.
- Unusual Manifestations of Infectious Mononucleosis. W. M. Fowler and R. T. Tidrick, Iowa City.—p. 548.
- Steatoirrhosis of Liver. L. C. McGee, F. Levy and J. E. Martin Jr., Elkins, W. Va.—p. 554.
- Human Infection with Bacillus Necrophorum. W. B. Martin, Norfolk, Va.—p. 567.
- "False" Positive Paul-Bunnell (Heterophile) Reaction? C. F. Kent, Kansas City, Mo.—p. 576.

American J. Digestive Diseases, Huntington, Ind.

7:365-400 (Sept.) 1940

- Body Build of Male Ulcer Patient. S. C. Robinson and M. Brucer, Chicago.—p. 365.
- *Evaluation of Meulengracht Regimen in Treatment of Bleeding Peptic Ulcer. J. Chasnoff, S. Leibowitz and R. Schwartz, New York.—p. 373.
- Functional Bowel Disturbance and Milk Allergy: Bedside Diagnosis. L. Cardon, Chicago.—p. 378.
- Studies in Human Biliary Physiology: V. Influence of Metabolizable and Nonmetabolizable Sugars on Liver Bile Secretion. M. Jacobi, I. C. Zuckerman, B. Kogut and B. Klein, Brooklyn.—p. 382.
- Secretory Studies in Whole Stomachs: Dilution Indicator Technique and Its Precision Measures. F. Hollander and J. Glickstein, New York.

Meulengracht Regimen in Bleeding Peptic Ulcer.—

The essential features of Meulengracht's method, according to Chasnoff and his associates, are that the patients are fed from the very onset of hemorrhage and that they receive liberal food allowance consisting of a puréed high caloric, high vitamin diet. Meulengracht had observed that many patients who had not sought medical aid and had continued on their usual diet apparently made uneventful recoveries, that some patients with protracted hemorrhage stopped bleeding when fed and that some patients, despite the most rigid dieting, died, apparently from exhaustion rather than from the extent of the hemorrhage. Thus he was prompted to change the treatment of bleeding peptic ulcer. Chasnoff and his collaborators present mortality statistics of all cases treated with the Meulengracht regimen which have appeared in the literature and compare these with the statistics of the older methods of treatment. The mortality rate with the Meulengracht method was much lower than the rates reported by those employing either the former medical regimen or surgery. Chasnoff and his co-workers employed the Meulengracht procedure for twenty-one patients, all of whom showed evidence of fairly extensive loss of blood. For comparative purposes the authors studied the results obtained in an unselected group of seventy-two patients treated with the older "starvation-Sippy" method. Among the twenty-one patients treated with the Meulengracht diet there was one death, or a mortality rate of 4.76 per cent. In the control group eight deaths occurred, which brings the mortality to 11.1 per cent. The patients receiving the liberal feeding of the Meulengracht diet manifested a well-being not noted in those under the older method of treatment. The duration of the hospitalization was not reduced by the Meulengracht method, for, whereas the patients on the "starvation-Sippy" diet averaged twenty-one days of hospitalization, those on the Meulengracht regimen averaged twenty-seven days. These figures differ from those reported by Meulengracht

and others. The percentage of perforation was higher for patients treated with the Meulengracht method than for those treated with other methods. The authors suggest that the increased feedings might possibly play a part.

American Journal of Diseases of Children, Chicago

60:471-782 (Sept.) 1940

- Systemic Reticulo-Endothelial Granuloma: Nonlipoid Reticulo-Endotheliosis and Schüller-Christian Disease. A. Wallgren, Göteborg, Sweden.—p. 471.
- Schilling Blood Count in Juvenile Lobar Pneumonia Treated with Sulfapyridine: Preliminary Report. J. L. Rogatz, New York.—p. 501.

Banana Intake and Nitrogen and Mineral Balances.—

Hunscher and her associates studied the effect on mineral balances of 100 or 200 Gm. daily of banana added to the diets of eight normal healthy children from 5 to 8 years of age. The children experienced three months of preliminary feeding and at least two weeks of training in metabolic technique. They lived in an environment that stimulated normal happy, healthful living. Each child was observed for from fifty to ninety consecutive days and no test interval was shorter than twenty days, the majority being from thirty to forty-five days in length. The data for the eight children for the preexperimental period is a total of 275 days and for the experimental period 285 days. A definite consistent metabolic response was noted to the increased banana intake. Data on the mineral accumulation of the eight children were averaged for each of the two periods. All the children grew during the study and showed consistent changes in metabolism in response to the inclusion of the larger quantity of banana in the diet. The daily addition of 100 Gm. of banana enhanced the rate of nitrogen storage from 17 to 22 mg. per kilogram of body weight daily, or from 3 to 4 per cent of the intake, although the nitrogen intake was reduced from 505 to 489 mg. per kilogram of body weight. Likewise the retentions of all the individual acid-base mineral elements were augmented if changed. The facts demonstrate that banana stimulated more rapid growth of both bone and soft tissue. The greatest difference between the alkaline-ash and acid-ash values of the diets without and with the additional 100 Gm. of banana was in their potassium content, 116 and 131 mg. per kilogram of body weight respectively. The apparent retention of this element increased from 8 to 10 mg. per kilogram daily. Although the daily calcium intake was reduced only by 1 mg. per kilogram of body weight, the apparent retention increased from 4 to 5 mg. per kilogram, indicating an enhanced rate of osseous development. The intake and retention of magnesium remained unchanged, and, although the sodium intake was reduced from 105 to 99 mg. per kilogram daily during the experimental period, the apparent

daily storage increased from 5 to 6 mg. per kilogram daily. By increasing the intake of banana the daily phosphorus intake was reduced by 3 mg. (from 53 to 50) per kilogram of body weight, yet the apparent retention was increased from 5 to 6 mg.; 70 per cent of the phosphorus retained is used in the formation of bone and 30 per cent becomes a component part of the soft tissue. The decreased intake of chlorine was accompanied by a higher retention. Although the daily intake of sulfur was reduced slightly (2 mg. per kilogram) its retention, essential to growth of soft tissue, increased from 1 to 4 per cent of the intake. As nitrogen is utilized it carries with it the major portion of the sulfur, from 30 to 40 per cent of the phosphorus retained and some of the potassium. There was a consistent relation between the percentage of nitrogen retained and the percentages of sulfur, phosphorus and potassium utilized. The increased storage of nitrogen was paralleled by augmented retentions of sulfur, phosphorus and potassium. An increase in the potassium:sodium ratios with the larger consumption of banana supports the belief that the formation of soft tissue was stimulated to a more rapid rate. Therefore banana in the diet has definite nutritive advantage but its *modus operandi* is still vague. The effect of the ascorbic acid or l-malic acid content of the fruit is not fully understood, but experimental work indicates that it stimulates excretion of citric acid and serves as an endogenous precursor of citric acid, which is considered a "physiologic metabolite."

Therapeutic Procedures for Scarlet Fever.—Rascoff and Nussbaum made a controlled study of 293 patients with scarlet fever so as to determine the value of sulfanilamide and scarlet fever antitoxin therapies singly and in combination. Depending on the severity of the illness each patient was placed in one of three groups: 125 patients of group 1 were admitted with "mild" (temperature of 100.5 F. or less with no toxicity or complications) scarlet fever and were treated symptomatically; 154 patients of group 2 were admitted with "moderately severe" (temperature of 101 F. or more, with toxicity and complications) scarlet fever and were treated, in rotation, with sulfanilamide, scarlet fever antitoxin, scarlet fever antitoxin or sulfanilamide or were given no therapy (control), and the fourteen patients of group 3 who were severely ill (temperature of 104 F. or more, with marked prostration and complications) were given scarlet fever antitoxin or scarlet fever antitoxin and sulfanilamide. The average age of group 1 patients was 8.6 years and the mean day of the illness on admission was 2.9. Signs present on admission were usually a slight rash, associated with a "strawberry" tongue, and a mild angina. A number of these patients were sick at home for several days and on admission were afebrile. The 125 patients with mild scarlet fever (41 per cent of all admissions) indicate the benign nature of the disease that is prevalent today. During the stay in the hospital adenitis developed in eight, otitis in two, tonsillitis in two and ethmoiditis in one. Four of the eight patients with adenitis received sulfanilamide and four did not. The course of the adenitis seemed to be unaffected by the therapy. The mean duration of the group 1 patients' stay in the hospital was 21.7 days. The average age of forty-one patients of group 2 receiving sulfanilamide was 7.4 years, the mean day of disease on admission 2.6, the mean duration of initial pyrexia while hospitalized was 2.6 days, there were six complications (three adenitis, two otitis media and one mastoiditis) and the mean duration of hospital days was 25.4. The respective figures for the forty patients receiving scarlet fever antitoxin were 10.5 years, 2.8, 2.5 eight (two adenitis, four otitis media, one arthritis and one nephritis) and 21.6 days; for the thirty-one given sulfanilamide and scarlet fever antitoxin they were 8.6 years, 3.0, 1.9, five (three adenitis and two otitis media) and 23.8, and for the forty-two given no treatment the figures were 7.8 years, 3.1, 2.5, thirteen (six adenitis, five otitis media, one tonsillitis and one ethmoiditis) and 25.5. The patients receiving the combined therapy apparently had a shorter duration of initial pyrexia (1.9 days) in the hospital, but this advantage was offset by the longer duration (three days) of the disease prior to admission to the hospital as compared to the other subgroups (2.6, 2.8 and 3.1 days). The greatest number of complications developed in patients receiving no therapy. The ages of the fourteen group 3 patients varied between 2 and 12 years, the day of illness on admission

from one to eight, only four patients had no complications (four had tonsillitis, one adenitis, one otitis media, one otitis media and arthritis, one petechial rash and tonsillitis, one otitis media and pneumonia and one otitis media and pneumonia with effusion) and days in the hospital varied from seven to 159. One patient died of sepsis thirty-six hours after admission. The patients of this group were seriously ill and every possible aid was given them and therefore most of them were given sulfanilamide and those with pulmonary complications received sulfapyridine. The results of the study show that sulfanilamide in scarlet fever is not as beneficial as it is in certain other streptococcal infections. It does not diminish the toxicity or duration of the fever. Frequently the malaise is intensified by the drug. In view of the prevailingly favorable opinion and its availability, sulfanilamide should be given in severe and moderately severe scarlet fever until evidence to the contrary is produced. Scarlet fever antitoxin or convalescent serum successfully combats the initial toxic phase and should be given early in the disease.

Preservation of Human Blood.—Kolmer preserved the blood of two adult donors belonging to groups A and B with four different preservatives for twenty-one days at from 4 to 6 C. Of the four preservatives employed, two were without carbohydrate (plain citrate and Moscow Institute of Hematology), one with dextrose (modified Rous-Turner) and one with dextrin (Maizels and Whittaker). The blood was examined within twenty-four hours and at the end of three, five, seven, ten, fourteen and twenty-one days for dehemoglobinization, fragility and preservation of erythrocytes and leukocytes. Special attention was paid to the neutrophils and the preservation of platelets, prothrombin, iso-agglutinins, complement and bactericidal activity. The two carbohydrate preservatives gave better protection of erythrocytes against dehemoglobinization, fragility and disintegration than the plain citrate and Moscow Institute of Hematology preservatives. The platelets and leukocytes were markedly reduced within three days with all four preservatives. The two carbohydrate preservatives gave somewhat better preservation than the two without dextrose or dextrin. The neutrophils were disintegrated. A slight decrease in prothrombin time (Howell) was observed with the plasmas of all preserved blood within the first twenty-four hours after its collection. This was due to disintegration of platelets. Dur-

ing the following three to seven days this was followed by an increase presumably due to loss of prothrombin. The iso-agglutinins showed no decrease during the first ten days with all four preservatives, but some diminution occurred after fourteen and twenty-one days. This was somewhat less marked with the two carbohydrate preservatives. Complement was well preserved by all four preservatives for the first seven to ten days. The bactericidal activity of the plasmas for *Bacillus typhosus* was well preserved by all four preservatives for seven days, following which rapid deterioration occurred.

Allergic Intestinal Bleeding in the Newborn.—The occurrence of intestinal hemorrhage as an allergic manifestation in infants, according to Rubin, has escaped description in the pediatric literature. During the last three years he has observed six such cases. The patients' histories are so dramatically identical, differing only as to minor details, as to form a definite clinical syndrome. There was in each instance a strong family history of allergy, usually bilateral, and cow's milk feeding was started immediately or within a few days after birth. Hunger or what was thought by the mother to be hunger was a constant complaint. This "hunger" probably represented abdominal discomfort and was manifested as "colic." Despite this, gain in weight was not impeded; in fact, it was above the average. The "colic" first appeared about three weeks after cow's milk feeding and became progressively worse. Within a few days loose stools appeared, soon to contain mucus and varying amounts of bright red blood. The blood promptly and completely disappeared from the stools within forty-eight hours after cow's milk was withdrawn from the diet. The mucus in the stools and the "colic" disappeared shortly afterward. In two of the children the "colicky" pains were associated with visible large gastric peristaltic waves indicative of pylorospasm. This was probably a part of the generalized gastrointestinal spasm which disappeared when the other symptoms were relieved. Diathetic eczema developed in all but one of the infants within a few months after the onset of the intestinal symptoms. One child also had asthma. Bleeding from any other part of the body was not observed. The bleeding and clotting times were normal. Bleeding from the intestinal tract did not recur after the cow's milk was withdrawn, except in one baby who also was sensitive to goat's milk. The melena disappeared when goat's milk was withdrawn and the child placed on a soybean mixture. The other infants tolerated goat's milk well.

Acetylsalicylic Acid Hypersensitivity.—Gardner and Blanton reviewed the histories of 467 private and clinic patients to determine the incidence of acetylsalicylic acid sensitization. More than half of the patients had asthma. All of them were regarded as having some sort of allergy. Salicylates may have influenced the development of allergic symptoms in five. A patient with angioneurotic edema involving the lips, cheeks and eyelids thought the taking of a tablet containing acetylsalicylic acid, acetanilid, potassium bromide and caffeine precipitated her attacks. Another patient thought the same product might cause an attack of asthma to develop. A patient with angioneurotic edema thought her attacks were induced by acetylsalicylic acid and a powder containing the ingredients of the aforementioned tablet. A patient with asthma complained of nausea after taking acetylsalicylic acid. Another reported that wheezing sometimes followed the use of salicylates. Dramatic consequences were not encountered. Fifty allergic patients were questioned whether any of the following symptoms occurred after taking acetylsalicylic acid: gastric discomfort, tachycardia, mental exhilaration, nausea, vomiting, diarrhea and ringing in the ears. They were also questioned about their experience in taking quinine. Forty-four of these fifty patients suffered from asthma, three had atopic dermatitis, one urticaria, one vasomotor rhinitis and one hay fever. All but three admitted taking acetylsalicylic acid or a compound containing it. Only four experienced unpleasant symptoms which they thought referable to it; two had rapid pulse and flushing, one had a depressed feeling and one complained of wakefulness. Of its effects on the allergic disorder itself, thirty-three stated they had never taken it for this purpose, five that it had had no effect and twelve thought it beneficial. In none were allergic symptoms provoked. It was found that seventeen had

never knowingly taken quinine. Those who had used it had done so only occasionally. Rashes had followed its use in two cases, and dizziness resulted in one instance. Allergic symptoms were not provoked. To throw further light on the hypersensitivity of allergic patients to acetylsalicylic acid the authors gave 5 grains (0.32 Gm.) of the drug to each of 103 consecutive patients admitted to the immunology clinic, after a negative history of such sensitivity was secured. Each patient was observed at the end of ten, thirty, sixty and 120 minutes. Fourteen maintained that "the medicine" had made them feel better. Two patients with asthma stated that they had a slight sense of constriction in the chest. The symptoms were transitory and may not have been the result of the drug. None of these 103 patients reacted violently. Of approximately 90,000 allergic patients seen by twenty-two allergists 170 had shown evidence of sensitivity to acetylsalicylic acid. This represents two per thousand. Among the same group, seventy-one instances of quinine sensitivity were reported. Study of the annual consumption of acetylsalicylic acid and quinine in this country shows that 5,143,672 pounds of acetylsalicylic acid was sold in the United States in 1937. This represents an average annual consumption of one half ounce (240 Gm.) or forty-eight tablets by each person. In the same year 3,458,009 ounces of quinine was consumed in this country. Therefore about seventeen times as much acetylsalicylic acid as quinine is consumed. If, out of a group of 90,000 allergic individuals, 170 were sensitive to acetylsalicylic acid and seventy-one to quinine, the chance of a given individual's being sensitive to quinine is seven times as great as is his chance of being sensitive to acetylsalicylic acid. These figures do not suggest that acetylsalicylic acid ranks first among allergy producing chemicals.

Renal Involvement in Disseminated Lupus Erythematosus.—Stickney and Keith summarize visceral involvement in disseminated lupus erythematosus and analyze the renal, clinical and necropsy manifestations observed in fifteen cases that came to postmortem at the Mayo Clinic between January 1913 and July 1939. The clinical and microscopic diagnosis was proved in every instance. Uremia was the terminal point of the disease in only four cases, with a blood urea of more than 60 mg. per hundred cubic centimeters. In these and in five others fairly constant albuminuria, microscopic hematuria and cylindruria were present. The urinary changes closely paralleled the severity of the cutaneous symptoms of most of the cases. All studies of renal function indicated good function until the final stages of the disease. In two cases albuminuria preceded the cutaneous lesions. In the others the cutaneous symptoms preceded the albuminuria, and the time between the

onset of albuminuria and death varied up to eighteen months. Cotton wool exudates were observed in the ocular fundi in one case and small hemorrhages in another. In three there was evidence of angiospasm in the retinal arterioles. The weights of all the kidneys were normal or greater than normal. Definite hypertrophy was encountered three times, and in none of these was there much interstitial edema. Hypertrophy of the liver was present in two cases. The absence of renal contraction is consistent with the fact that severe hypertension was not found. There were no significant changes in the renal arteries and arterioles. A typical pyelonephritis was not found. The most common microscopic observation was an increase in the endothelial cells of the glomerular tufts with a reduction of the erythrocytes in the capillary loops. Some degree of proliferation of endothelial cells was present in six cases. Hyaline eosin-staining material in the glomerular capillaries was observed in five cases and this probably represented a degenerative process. Definite fibers, which stained like and apparently were derived from the basement membrane, were seen within the glomerular capillaries in five cases in sections stained with azocarmine. Tubular damage, except in regions related to infarction, was minimal, although a few hyaline and granular casts were found in several cases. No significant deposit of lipid or amyloidosis was found. For comparison with the described renal changes, renal sections of eighty-five patients dying of various other causes and coming to necropsy were studied. Eleven of these had renal changes comparable to those seen in lupus erythematosus. These patients make up the "control series." The renal changes in the control series, which did not include any with known renal disease, were as marked as most of those seen in the lupus erythematosus series, but the intracapillary hyaline changes were not seen in the control group. These intracapillary hyaline changes were similar to the lesion seen frequently in bacterial endocarditis. If in disseminated lupus erythematosus the renal disorder is an acute glomerulonephritis, it must be concluded that its duration does not coincide with that of the albuminuria and hematuria but that it is a terminal process. Other possibilities might be that the disorder is a peculiar variety of nephritis with a low virulence or that it is a degenerative process secondary to a toxic debilitating disease.

Protamine Zinc Insulin.—Tolstoi and Weber observed for fifty and sixty days respectively two hospitalized patients who received one dose of protamine zinc insulin daily and a diet of 1,640 calories, composed of 75 Gm. of protein, 60 Gm. of fat and 200 Gm. of carbohydrate. They concluded that satisfactory treatment of diabetes mellitus with protamine zinc insulin involved the following criteria: (1) maintenance of weight, (2) absence of ketone bodies in the urine and (3) freedom from thirst, polyuria, frequency of urination, hunger, weakness, fatigue, polyphagia, pruritus and visual disturbances. They felt that it was the utilization and not the excretion of carbohydrates which was of prime importance and that glycosuria was not an undesirable feature, as it protected the patient from reactions. They have treated eighty-four ambulatory patients with one daily injection of insulin for at least one year and made no effort to maintain the urine free from sugar. Only twenty-seven had persistent glycosuria throughout the period of observation. These twenty-seven were in good health and socially and economically useful. Not only did the majority of them maintain their weight but some gained weight, even though heavy glycosuria was almost always present. There were no complaints or symptoms associated with the glycosuria, and infections were no more frequent than in those whose urine was usually free from sugar. All these patients enjoyed much more freedom, as there was no necessity for careful dietary measurements nor did they need to carry their syringe and insulin. They administered the insulin to themselves every morning, were not singled out as a group apart from their fellow men, and their habits of living approximated the normal ones. There is no evidence to show that, with protamine zinc insulin, utilization of carbohydrates does not take place in spite of hyperglycemia and glycosuria. Glycosuria has so dominated the study of the treatment of diabetes that the factor of utilization has been almost totally ignored. It has been established by Allen and Du Bois and their associates that for short periods the diabetic patient, irrespective

of the severity of the disorder, is capable of physiologically utilizing carbohydrate. Today the physiologic utilization of carbohydrates can be prolonged by insulin. Therefore hyperglycemia and glycosuria must be of secondary importance. The most important and physiologic basis for satisfactory treatment appears to be not how much sugar is excreted but how much is metabolized. Bridge and Winter have demonstrated that in an insulin-treated diabetic person carbohydrate is utilized in the presence of hyperglycemia and sequential glycosuria. They conclude that neither the value for blood sugar nor the degree of glycosuria is an adequate criterion for the regulation of diabetes. Their conclusion is particularly applicable to patients treated with protamine zinc insulin. The authors feel that if a state of carbohydrate utilization can be maintained in the diabetic person (and this is readily accomplished by the use of protamine zinc insulin) a physiologic state has been created and that the guiding principles for such a status in the presence of glycosuria and hyperglycemia are the three criteria listed.

Vitamin B Therapy for Diabetes.—Good results have been claimed from the administration of thiamine and ascorbic acid to persons with diabetes. Owens and his co-workers have undertaken a similar study of twenty-five diabetic patients well standardized for from six to eighteen months prior to vitamin therapy. Under conditions of adequate control, thiamine and riboflavin were found to produce no noticeable alteration in the diabetic state except for amelioration of neuritic pain by thiamine. Vitamin therapy for diabetes would seem to be without basis in fact. Diabetic patients regularly show a reduction in insulin need as the months of adequate control pass and eventually a basic level is reached requiring no change unless infection or other intercurrent disease upsets the established balance. Therefore for well controlled diabetes there appears to be no need for thiamine or riboflavin beyond the amounts present in ordinary diabetic diets, except for diabetic neuritis, on which thiamine has almost a specific effect. In most cases of such neuritis improvement also occurs when the diabetes is controlled by proper diet and insulin. This might suggest a thiamine deficiency during the uncontrolled period, but the possibility also exists that the improvement in neuritis results only from increased tissue combustion of sugar under insulin therapy and not from a specific lack of thiamine. Actual and severe vitamin deficiency may play a part in diabetic coma when food and vitamin intake ceases and the presence of fever enhances combustion. The usual methods of treating coma do not provide for any replenishment of vitamins. The most severe evidences of damage due to coma occur in the tissues with the highest rate of combustion and therefore with the greatest need for the vitamin B fractions—the brain, the kidney and the heart muscle. Diabetic coma still presents an unsolved clinical problem, with a fatality rate as high as in the early days of insulin therapy.

Aviation Deafness.—Campbell and Hargreaves classify the deafness of aviators according to its cause: (1) acute fatigue of the end organ of hearing and related structures, (2) chronic accumulative fatigue of the end organ and related structures, (3) conduction deafness due to changes in pressure in the ear and (4) chronic conduction deafness due to alteration in the tissue resulting from faulty ventilation of the middle ear. The first two classifications are manifested by a decrease in hearing

acuity in the neighborhood of the 4,096 area—a perception deafness—and the last two by a decrease in the lower frequencies (from 128 to 1,024), a form of conduction deafness. Both types of deafness may be mixed to give any form of audiogram, which may be altered by the usual changes and hazards coincident with life. Fatigue of the end organ of hearing is due to noise and the effect of other vibratory energies inherent with flight. The 4,096 area is peculiarly vulnerable because of its exposed position and possibly altered blood supply. Altitudinal decrease in oxygen may be a factor in its production. Physiologic or pathologic failure of the middle ear to be properly ventilated during altitudinal changes in pressure leads to acute or chronic changes in the middle ear, with the usual picture of conduction deafness. Rapid advance in aircraft design (sound-proof cabins) and in flight regulation and education will decrease aviation deafness, making the problem less serious in the future.

Adrenal Cortex Extract and Salt for Severe Infections.—Perla and Marmorston state that during the last two years adrenal cortex extract was used in the private practice of Marmorston in the treatment of seventeen cases of bronchopneumonia, one case of therapeutic malaria for dementia paralytica and six instances of severe grip. The general physiologic

care of severe infection was carried out for all these patients. In addition, adrenal cortex extract in amounts of from 2 to 5 cc. twice a day intramuscularly or subcutaneously was administered from the first day of observation and continued for two or three weeks until recovery. The apparent effects of the extract were as follows: 1. The normal blood pressure with prevention of collapse was maintained. 2. There was an evident decrease of toxicity. 3. Distention was avoided, the appetite improved and the sense of well being was increased. 4. There was an apparent shortening of the period of convalescence. In the cases with pneumonia, the signs in the chest did not clear up sooner than is usually anticipated. Sulfapyridine was given to three patients (two with pneumococcal infection and one with *Streptococcus viridans* pneumonia) but in two it was abandoned because of severe toxic symptoms (rash, rise in temperature and vomiting). The blood pressure of these patients was maintained though the psychic depressive effect of the sulfapyridine persisted. In several of the patients, periods of collapse were readily combated by the adrenal cortex extract, given intramuscularly in amounts of from 3 to 5 cc. every six hours night and day. The patient in whom malaria was induced went into profound collapse following the third chill. The blood pressure dropped to 60 systolic, 40 diastolic. Epinephrine had only a transient effect. Adrenal cortex extract was then administered for the first time, 5 cc. intravenously and maintained at the rate of from 3 to 5 cc. twice a day intramuscularly. The blood pressure rose promptly to 110/80 and was maintained. One hour after the first injection the patient sat up in bed, said he felt fine and asked for food. Similar experiences have been repeated in other cases. The diagnosis of the seventeen cases of bronchopneumonia was confirmed by x-ray examination. Only a single death occurred, that of a woman of 65 with a recent myocardial infarct complicated by bronchopneumonia. Two men and one woman more than 75 years of age made uneventful recoveries from bilateral bronchopneumonic processes. No complications occurred among the sixteen patients who recovered. The authors conclude that a quantitative evaluation of the extract as an adjunct in the treatment of severe infections is difficult. No definite chemical standard of its action on patients with intact adrenals who are given moderate doses of the extract is available. Nevertheless the clinical value is apparent and an extensive trial is indicated.

Local Use of Sulfathiazole for Staphylococcal Infections.—Spink and Paine applied sulfathiazole directly to the staphylococcal lesions of sixteen patients. *Staphylococcus aureus* was isolated from every lesion. Depending on the site of the lesion, immobilization and elevation of the infected area were used to enhance circulation. Adequate surgical drainage and débridement of devitalized tissue were utilized. Sulfathiazole was applied directly to the lesions to permit a much higher local concentration of the drug than could be obtained when given orally. Acutely ill patients were also given sulfathiazole orally. This procedure was directed against a possible bacteremia and to prevent an extension of the primary focus. To prevent the inhibitory action of bacteria, exudate and necrotic tissue on sulfathiazole the wounds were irrigated frequently with warm saline solution and, following each irrigation, sulfathiazole was used in the wound in crystal form, 1 per cent aqueous solution or as wet packs. In a few cases, particularly those in which there were carbuncles, irrigations with hypochlorite solution aided considerably in removing purulent and sloughing material. The results were as follows: Of the four cases of carbuncle, three granulated in without cutaneous grafts and the results in the other one is doubtful; the six operative wound infections healed and became sterile; in one, decubitus ulcer grafts were successful after two previous attempts had failed, one corneal ulcer healed and became sterile, one of two chronic osteomyelitis lesions showed extensive osseous repair and the result in the other is too recent to draw any conclusion, the number of organisms was reduced in one pyopneumothorax but the cavity is not sterilized and there was improvement of the subcutaneous abscess but the patient died of leukemia.

Management of Tetanus.—Heersema reports the first case of tetanus in which hyperpyrexia was used in its management. In eight days the patient's condition had progressed to the point of acute continuous pain and inability to swallow, when hyperpyrexia was suggested by Woltman in the hope of increasing the neutralizing effect of the antitoxin. The patient was given four hours of artificial fever produced by physical means, with a systemic temperature ranging between 105 and 106 F. He tolerated the fever treatment very well after the first hour and it had the definite effect of relaxing his muscles. Because of the beneficial effect of relaxation he was placed in a pack at the end of the second fever session and allowed to

cool off over a period of four or five hours. This continued throughout twelve fever sessions. Each of the sessions was tolerated progressively better. They were given at intervals of approximately two days. When the patient was seen two and a half months after the nail wound which caused the tetanus, he reported complete recovery. The method must rest for the present on its merits as a means of symptomatic control of the painful spasms of tetanus which constitute, through exhaustion, the greatest problem and danger of this infection. Relief from the terrifying spasms, even at the cost of any discomfort from the hyperpyrexia, was welcomed by the patient and throughout the entire course he was able to be more cooperative on smaller amounts of hypnotics than is usually experienced. The more cooperative attitude of the patient is believed largely attributable to his relative freedom from fear and panic during the sessions of fever. The author believes that the symptomatic relief obtained is sufficient to warrant further trial of the method. The possible relationship of ascorbic acid and hyperpyrexia to tetanus toxin is suggested in that the fever may speed up an ascorbic acid reaction of detoxification of the tetanus infection.

Tuberculosilicosis.—Benson reports observations on 207 employees in the granite industry who had silicosis complicated by pulmonary tuberculosis. These observations point to free silica as the substance which increases the liability to tuberculous infection. The silica is believed to act as a chemical irritant of pulmonary tissue. Evidence points to a decrease in tissue resistance to tubercle bacilli in cases of silicosis. The diagnosis of tuberculosilicosis requires the existence of a silicosis hazard. The occupational history must show the presence of dangerous concentrations of free silica in the breathing air level. This danger limit in the granite industry is usually set at 10,000,000 particles per cubic foot of air. Average dust counts in the granite-cutting trade have ranged from approximately 60,000,000 particles per cubic foot of air for hand pneumatic tool operators to less than 10,000,000 for attendant laborers. Another contribution toward the diagnosis of tuberculosilicosis is the detection of a high local rate of pulmonary tuberculosis in an industry and its environment. The onset of tuberculous infection in silicotic patients may be accompanied by no symptoms, by a general indisposition or by an explosive widespread dissemination of the disease process. The com-

monest symptom is dyspnea. The patient becomes conscious of a breathing effort that he had not noticed previously. Cough, expectoration, chest pain and hemoptysis often accompany the onset of tuberculous infection in silicosis. In the roentgenologic picture of tuberculosis the linear apical shadows that may be present seem to be broader than those noted in cases of pulmonary tuberculosis without silicosis. Unless these are in the top lung fields, tuberculosis with silicosis is difficult to differentiate from conglomerate silicosis. The only absolute clinical proof of tuberculosis is the discovery of tubercle bacilli in the sputum. There appears to be high correlation between the x-ray evidence of cavities in tuberculosilicosis and tubercle bacilli in the sputum. The commonest clinical form of tuberculosilicosis seen in granite workers is that in which there is a slow progression of the infectious process. Many of these cases suggest that silicosis is superimposed on inactive tuberculosis. The chronic course seems to follow the reactivation of the old lesions and begins chiefly in the upper lobes and extends to the lower fields. The consolidation increases yearly, and basal infiltration is quite common. There are cough, dyspnea, distorted thorax and later purulent expectoration. The patients are usually afebrile but have toxic symptoms off and on. The sputum is ordinarily negative until the terminal months but may be positive intermittently. Preemployment examinations to detect respiratory disease before the worker can be exposed to silica dust are of value in the prophylaxis of tuberculosilicosis. The treatment of tuberculosilicosis is the same as that of pulmonary tuberculosis.

Hypotension: The Ideal Normal Blood Pressure.—According to Robinson, hypotension has been looked on as a disease entity. The "low blood pressure" person was described as one who lacked stamina, tired easily, complained of cold extremities and showed an inability to do prolonged mental or physical work. The author is not concerned with such diseases as Addison's disease, coronary thrombosis, status lymphaticus, shock or infectious diseases which may be accompanied by low blood pressure. The dividing line between normal and hypotensive pressure has never been unanimously agreed on. The upper limit of systolic hypotension has been put as high as 120 mm. and as low as 90 mm. Because the 110 mm. level is chosen by about half the observers, the author has selected it as the point below which all pressures are tentatively called hypotensive. He does not imply that this level makes any significant division in the realm of blood pressure. The level of diastolic pressure below which hypotension is said to exist is not so frequently suggested. Because the 70 mm. diastolic level corresponds statistically to the 110 mm. systolic level, it has been selected for the purpose of this report as the upper level of diastolic hypotension. Hypotension is not a rare occurrence. In a series of 10,883 persons representative of an urban group the age standardized incidence of systolic pressures under 110 mm. was 25 per cent and that of diastolic hypotension 34 per cent. Robinson finds that age has a negligible effect on the distribution of low systolic blood pressure in men up to the seventh decade; thereafter the incidence decreases. Young women have a much higher incidence of low blood pressure than do men, and old women have about the same incidence as do old men. Hypotension is commonest among the linear built or narrow chested type. It is two or three times commoner among lightweight than among heavy-weight men and women. Low blood pressures show a smaller and less erratic yearly variation and do not vary over as great a range as do high pressures. They do not tend to rise with age; rather they maintain an even level. They are associated with a mortality rate lower than that of average pressures. The symptoms usually ascribed to hypotension are in reality commoner among hypertensive persons. There are no symptoms peculiar to or due to low blood pressure. Neither fatigue nor vitality is a function of the level of blood pressure; rather they are related to the daily physical activity of the individual. In fact, those persons noted for endurance, vitality and well-being, trained athletes, farmers and other active groups, are also noted for their high incidence of low blood pressure. Hypotension is not a disease; it is an ideal blood pressure level.

Bulgarian Belladonna and Other Medication in Chronic Encephalitis.—According to Neal and Dillenberg, the Matheson Commission for encephalitis research began about two years ago the use of white wine decoction of Bulgarian belladonna in treating patients with chronic encephalitis. When it was found that this decoction deteriorated on standing, a tablet was prepared to insure a stable preparation. Approximately 100 patients have been treated with these preparations and with the tablets. Practically all of these patients had previously tried other forms of symptomatic treatment, such as scopolamine, stramonium, amphetamine sulfate or combinations of these medications. The results with the Bulgarian belladonna were far superior to those obtained with any other form of symptomatic treatment. About one third can be considered greatly improved, one half moderately improved and the remainder slightly improved. Many of the patients have been under treatment for at least a year and a half, and the improvement has been maintained. In certain cases the improvement is increasing. It was possible to make a comparative study between twenty-three patients treated with tablets of Bulgarian belladonna and twenty-one treated with a synthetic preparation containing about 0.5 mg. of alkaloids in the following combination: hyoscyamine 0.45 mg., atropine 0.037 mg. and scopolamine 0.012 mg. All patients were in a far advanced stage of chronic encephalitis and all had previously received various forms of medication. The severity of encephalitis was as nearly equal as possible in the two groups. The results obtained with the tablets of Bulgarian belladonna were far superior to those with the synthetic preparation. All except three of them showed subjective improvement. They felt stronger, slept better, had less feeling of tension and were more cheerful and cooperative. Objectively there was an improved facial expression, less spasticity and tremor, greater facility in motion, and improvement in speech. Increased salivation was entirely relieved in practically all cases. The improvement of the patients treated with the synthetic preparation was similar but not so marked. The synthetic preparation produced toxic effects more frequently, more severely and with smaller doses than did the Bulgarian belladonna. It is interesting that, when the comparative study was ended and the patients were returned to the previous medication, almost all of those treated with tablets of Bulgarian belladonna requested that these tablets be continued, whereas the patients who had received the synthetic preparation for the most part accepted the return to the former medication without comment. The authors conclude that Bulgarian belladonna is the most beneficial drug available in the treatment of chronic encephalitis.

Picrotoxin Treatment of Barbiturate Poisoning.—Reifenstein calls attention to a previous publication in which he described two cases of barbiturate poisoning treated with picrotoxin and presents a third case in which recovery from a lethal dose of phenobarbital occurred with no antidotal treatment except picrotoxin. The patient was given one of the largest reported doses of picrotoxin (559 mg.) without harmful effect and he failed to exhibit the depressed blood pressure usually observed in acute barbiturate poisoning. He was 25 years of age, weighed 146 pounds (66 Kg.) and had taken from 6 to 8 Gm. of phenobarbital with suicidal intent. He remained untreated for fourteen hours and was found in a deep coma. He

failed to respond to physical stimulation. He was treated continuously for seventy-eight hours with intravenous injection of picrotoxin, alternating with intravenous administration of sucrose. He received a total of 559 mg. of picrotoxin and 1,250 cc. of a 50 per cent solution of sucrose. This case furnished additional evidence that picrotoxin is an effective antidote of acute barbiturate poisoning.

Cancer Among Male Employees of Oil Refining Company.—Gafafer and Sitgreaves studied the records of the members of a sick benefit plan connected with an oil refining company. The study covers a period of six years, from 1933 to 1938, during which there was approximately 60,000 years of membership for the male employees. There were seventy cases of cancer, forty-six of which ended in death. The cases which did not end in death terminated in recovery or insufficient improvement for return to work. The forty-six deaths yield an average annual death rate of 0.78 per thousand. The population exposed represents an age distribution ranging approximately from 15 to 69 years. The calculated crude death rate from cancer for white males from 15 to 69 years of age throughout the entire United States for the years 1933 to 1937 is 0.96 per thousand, while the experience of the industrial department of a large life insurance company for 1935 gives a rate of 0.86. Although previous studies have indicated that certain types of mineral oils possess carcinogenic activity, the present experience is therefore not unfavorable. Relatively more cancers of the digestive system occurred among the employees studied (thirty-two, or 69.6 per cent of the deaths) than occurs among the total population. The proportion of cancers of the genitourinary system was somewhat less, 8.7 per cent as compared to 15 per cent. There were five cancers of the respiratory system, three of the buccal cavity and two of other sites. Study of the duration of disability of all cases reveals that among the thirteen cases of cancer of the oral region seven caused disability of less than twenty-eight days and that none of these were fatal. One death was recorded among three cases lasting from twenty-nine to ninety-one days, and the two patients whose disability lasted longer than 182 days died. A corresponding

relationship is observed for cancer of the trunk and extremities. However, the reverse is true for cancer of the lung. The five deaths among the eight cases recorded for this site all occurred during the interval of from twenty-nine to 182 days. If the average durations of the fatal and of the nonfatal cases are arranged in order of decreasing magnitude by specific site, the two arrays show that the lungs come first in the array of nonfatal cases with an average case duration of 359.3 days. This site is last in the array of fatal cases with an average case duration of 90.6 days. The reverse holds for cancer of the trunk and extremities and of the oral region. These are first and second in the arrangement of fatal cases with average durations of 263 and 249 days respectively and at the bottom of the array of nonfatal cases, with average durations of seventy and 363 days.

Epidemiology of Oxyuriasis.—Sawitz and his associates examined 491 inmates of six children's homes for Enterobius vermicularis. The National Institute of Health swabs were used for examinations. The total incidence of infection was 74.3 per cent; the highest in one home being 96.9 per cent, and the lowest in another was 15.9 per cent. The incidence among the 278 white boys was 89.6 per cent, among the eighty-seven white girls 60.9 per cent, among the sixty-three Negro boys 84.1 per cent and among the sixty-three Negro girls it was 15.9 per cent. The incidence by age showed an increase during the first six years of life. It remained high until the fourteenth year and then decreased. The incidence by age and sex showed a slightly lower incidence in girls than in boys under comparable environmental conditions in the first six years of life, an equally high incidence up to nine years and then the incidence decreased among girls but remained high among boys until the age of 15 or more. The incidence by age and race showed no difference if groups of the same age and sex and under the same environmental conditions were compared. Among children of comparable age it was more than twice as high among those in large dormitories as among those in single or double rooms. Enterobius eggs were recovered from pajama pants, bed sheets and ledges of pillars, windows and doors of dormitories and toilet rooms. The usual hygienic measures such as frequent house cleaning, change of underwear and bed sheets and frequent bathing did not interrupt the important transmission routes of Enterobius. A cleanliness period of six weeks in one home did not result in any decrease in the infection. The Enterobius incidence among children biting their fingernails was no greater than among others. No correlation was found between Enterobius incidence and the amount of money spent for the maintenance of

the institution or for the food of the children. The important transmission route of *Enterobius vermicularis* appears to be by direct contact with infected individuals or contaminated objects. The incidence by age is tentatively explained as follows: Infection in the first year of life is exceptional because babies usually remain in separate beds and have no prolonged contact with other children. From 1 through 5 years of age the incidence increases with age, but the children are washed and taken care of. From 6 years on the incidence runs highest as the children come in close contact with one another during school or play, and although they wash themselves they do not do so effectively. The incidence continues to be high unless separate bedrooms or rigid personal cleanliness control the infection. These factors become operative earlier in the lives of girls than of boys.

Pinworm Infection in North Carolina.—Brown and his colleagues endeavored to determine the prevalence of pinworm infection in North Carolina by examining the following groups of individuals: (1) 132 white boys from 8 to 14 years of age from the Charlotte Observer Fresh Air Camp, (2) 100 white and Negro patients of all ages at the Duke University Hospital outpatient clinic who were not seeking aid due to symptoms referable to pinworms and (3) 118 male students aged from 17 to 31 years attending the University of North Carolina. All specimens were obtained by means of the National Institute of Health swab. Single swab examinations made on the 132 white boys revealed a pinworm infection rate of 32.8 per cent. Considerable variation was encountered; for example, 25 per cent of the 10 year old boys were found to be infected, while the 13 year old boys showed a rate of 50 per cent. Of the 100 patients sixty-seven were white and thirty-three were Negroes. Both children and adults were included in the group which was definitely of the lower income group. A total of 7.4 per cent of the white patients were infected. However, a rate of 16.6 per cent was revealed among the white patients between 0 and 19 years of age, while only 2.3 per cent of those 20 years or older were infected. Not a single pinworm infection was found among the thirty-three Negroes examined and likewise none among the university students, although special care was taken in their examination. Additional epidemiologic investigations are needed to show why pinworm infection was not found among the Negro outpatients. It is possible that the Negro may be partially immune to pinworm infection as he is to hookworm infection.

Treatment of Massive Hemorrhage from Peptic Ulcer.—Stone reviews the twenty year experience of the Mason Clinic with massive hemorrhage from peptic ulcer. A total of fifty-seven such cases among the 1,076 examined for peptic ulcer were so designated because they were sufficiently severe to produce hematemesis or melena, fall in blood pressure, pallor and perhaps syncope. There were nine deaths, a mortality of 15 per cent and an incidence of seven massive hemorrhages and one death from hemorrhage for each 10,000 admissions to the clinic. This explains why death from massive hemorrhage has been considered rare in a practice limited to private patients. Thirty-five of the patients were less than 50 years of age and three of these died, one of hemorrhage from a jejunal ulcer and two from unrelated causes after the cessation of bleeding but while the patients were still in the hospital. Six of the

remaining twenty-two patients who were more than 50 years of age died, giving a mortality of 27 per cent for this age group. All these patients died of exsanguination, two following late surgery. The author is in accord with the many internists and surgeons who now believe that early surgical intervention is indicated in these older patients. However, the true value of early surgical intervention will not become apparent until comparative figures are available for this age group. There are certain limitations beyond which surgery cannot go. Some patients in this group will die of hemorrhage before surgical intervention is possible. Many of the patients in this older group will be very poor surgical risks at best, and their chance of surviving radical surgery will be less than the probable two in three chances of surviving a profuse hemorrhage. Surgical judgment must play a great part in selecting them for emergency operation as well as in the choice of the operative procedure. The surgeon must be willing to accept a high risk if he hopes to reduce a mortality of 30 per cent. Technical difficulties will at times prevent satisfactory and permanent control of hemorrhage. The almost always fatal result among patients seen after prolonged hemorrhage justifies an attempt to control the hemorrhage by some direct surgical procedure. Recent advances in the care of depleted patients and in the prevention of complications may improve the results of late surgical intervention in the course of bleeding. The approximate mortality of 30 per cent among patients more than 50 years of age indicates the seriousness of massive hemorrhage from peptic ulcer and is a definite challenge to those who advocate conservative treatment for these patients. The infrequency of cases of massive hemorrhage from peptic ulcer in private practice suggests that an approach to this problem must be based largely on the combined reports from other sources. Recurrent profuse hemorrhage demands surgical intervention.

Karaya and Related Gums as Causes of Atopy.—Feinberg and Schoenkerman encountered ten patients whose allergic symptoms were attributable to karaya and related gums. The ten patients were women; the source of exposure of eight of them was the hair-setting fluid or powder used in their hair; one was a hair dresser and the source of contact of the other one was the women visiting her shop after having their hair dressed in a nearby establishment. Of these ten patients, eight were tested with acacia; only one gave a slight positive reaction. Nine were tested with tragacanth; two showed slightly positive reactions. In four karaya gum was the sole cause of the allergic symptoms; in the others, additional causes played a part, particularly pollen and fungi. The allergic symptoms of three of these women were entirely those of rhinitis; asthma was the predominant symptom of six, although rhinitis was also present in some of the latter. One of the women with asthma also had a dermatitis of the face and scalp which was attributable to the gum. The sole complaint of one woman was a dermatitis of the face and neck. Although the dermatitis was caused by contact it was of the atopic variety, as indicated by the presence of the positive scratch test and of circulating reagins. Eight women obtained a complete cure or subsidence of symptoms due to this allergen by substitution of other ingredients in the preparations employed for the hair. Desensitization, with only partial results, was employed for one, and lack of cooperation and the presence of complicating allergy in the remaining patient resulted in failure. The authors state that, because of the wide use of these materials in cosmetics, numerous foods, pastes, constipation remedies and many other products many more instances of this type of allergy will undoubtedly be found. The possibility of other water soluble gums in industry as a source of allergy must not be overlooked.

Pulmonary Tuberculosis in Recruits.—According to Cooper, the discovery of cadets with active pulmonary tuberculosis induced the medical directorate at the Australian army headquarters to consider the possibilities of a mass survey of recruits. He points out that the microroentgenographic method developed chiefly by Manuel de Abreu in Rio de Janeiro is especially valuable for mass examinations. In an appendix he describes the equipment used for the miniature x-ray examination and in another one the procedure employed for the miniature roentgenography of the chests of recruits. Every small film (35 mm.) is examined by at least one physician and one radiologist. Usually more than two medical men are present during the viewing of films. Whenever anything abnormal is detected in the 35 mm. film a large roentgenogram is taken next day. No man is rejected on the small film alone. The 14 by 17 inch film is reported on by a physician and a radiologist, and the large film, with the report, is made available to a medical board consisting of two physicians. No man is discharged from the Forces on x-ray observations alone: in every instance in which x-ray examination suggests tuberculosis a case history is recorded and the chest is reexamined by two physicians. If any sputum can be obtained it is examined for tubercle bacilli by staining and culture. About 9,000 recruits were examined personally by the author and this report deals with the conclusions drawn from these 9,000 films. It takes some time to become accustomed to reading the small films. Both the intensity of illumination and the character of the surface on which the films are projected make an appreciable difference. Each radiologist has an optimal distance from the projection screen at which the image appears most like the large chest films to which he is accustomed. Some abnormalities are detected more easily at a distance of from 8 to 10 feet, but for routine reporting a distance of 6 feet suits most. The small films can be projected up to a size of approximately 12 by 14 inches without loss of detail. Enlargement to the 14 by 17 inch size is not always possible. The maximum number of 35 mm. films reported by a group was about 1,000 in an evening of three hours. As fatigue occurs rapidly the practice was adopted of one radiologist reporting on not more than from seventy to 100 successive chests without relief by one of the others present. A comparison between the 35 mm. pictures and the 14 by 17 inch film demonstrates that there are factors operating in the micro-roentgenographic technic which result in variations from what is generally regarded as a normal chest roentgenogram. In 541, or 6 per cent, of the 9,000 recruits 14 by 17 inch films were ordered. Four thousand eight hundred and thirty (54 per cent) of the microroentgenograms showed evidence of hilar calcification suggestive of a healed primary tuberculous infection; 120 (1.33 per cent) showed evidence in the lung fields of past or present tuberculous infection of the secondary adult type of tuberculosis; forty-nine recruits (0.55 per cent) showed evidence of active pulmonary tuberculosis. In addition to the cases of pulmonary tuberculosis, other lesions were detected such as a large cyst, two mediastinal neoplasms, several aneurysms of the aorta, congenital polycystic disease and nontuberculous pneumonitis.

Serum and Plasma in Treatment of Hemorrhage.—The stability of serum or plasma and the growing body of evidence that pooled samples can be safely used in human patients of any blood type prompted Magladery and his collaborators to

reinvestigate the extent to which these fluids can replace whole blood in the treatment of animals with acute hemorrhage. The study deals with results obtained in fifty-five dogs of from 5 to 15 Kg. in weight. Anesthesia was produced and the animals were prepared in the usual way for the recording of blood pressure and the administration of fluids. After the blood pressure had reached a reasonably steady level and control blood samples had been obtained, bleeding was begun through an arterial cannula at a rate which produced a gradual reduction of the pressure to about 30 mm. of mercury. It soon became apparent that neither the weight of the animal nor its initial blood pressure afforded any precise indication of the quantity of blood which had to be removed before typical post-hemorrhagic shock appeared. When enough blood was removed this condition usually developed. It was characterized by a low body temperature and a failure of the blood pressure to rise above the level of from 30 to 50 mm. of mercury after cessation of bleeding. When death was imminent, treatment consisting of application of heat and the intravenous injection of serum or plasma was instituted. Determinations of blood volumes were made by the dye method of Gibson and Evans as adapted to the photoelectric colorimeter (Gibson and Evelyn, 1938), but after many control experiments it became apparent that samples taken more than thirty minutes after the injection of the dye (T 1824) gave unreliable results when the animal was in posthemorrhagic shock. For this reason satisfactory blood volume determinations were secured in only eleven experiments. Cell volumes were determined by the hematocrit. In untreated hemorrhage no animal losing more than 55 per cent of its calculated blood volume recovered without some form of treatment. An attempt was made to compare the efficacy of various blood substitutes. Isotonic saline, hypertonic saline and dextrose solutions were tested. Even when administered in large quantities these solutions produced rises in blood pressure which were so evanescent that they were considered to have relatively little value as blood substitutes. In animals which were treated with their own heparinized blood, it was found that about 40 per cent of the removed blood had to be replaced to secure recovery of an animal in posthemorrhagic shock. Comparable volumes of serum or plasma produce equally satisfactory results. Thus the observations indicate that the volume of the red cells restored to the animal is more important than their oxygen-carrying capacity and that serum and plasma, which can be stored for long periods, are effective blood substitutes for the treatment of hemorrhage. The authors also observed the importance of administering blood or blood substitutes at a rapid rate (from 50 to 100 cc. a minute) and as soon as possible after the hemorrhage.

Effects of High Explosive Blast on Lungs.—Dean and his collaborators present a series of twenty-seven cases in which treatment was being given for burns or otitis resulting from the bursting of high explosive quarters. Special attention was given to the state of the lungs. In two cases the question of exposure to blast

Only six patients complained of symptoms related to the chest; sixteen showed some abnormal physical signs and fourteen showed abnormal radiologic appearances. Evidence of serious pathologic changes in the chest was absent in all but two cases; in one of these the signs of collapse of a lobe of the lung were present, in the other the signs of a patchy consolidation of the bronchopneumonic type. The relative importance of the three factors to which the patients were exposed—blast, burns and immersion—in relation to the chest conditions is impossible to assess. It will be difficult to find cases in which there are no external injuries. Immersion may have played an important part in one case but this experience occurred in only three and the other two showed neither symptoms nor signs of chest involvement. The authors emphasize the relative disproportion in frequency between the symptoms and physical signs in the cases studied. This may be due to the fact that all were subject of serious injuries which would tend to direct their attention away from the chest. Since chest complications may arise after explosion blast without definite warning symptoms, routine examinations should be performed even in those who are apparently unaffected by the blast. The physical signs that may be expected are diminished movement of the diaphragm, fullness of the chest giving it an emphysematous appearance, and impairment of resonance at one or both bases, with or without crepitations. The frequency of a "blown up" or ballooned appearance of the chest, especially at the lower costal margins after such injuries, may be related to the posture the patients adopted in bed or to the presence of an already existing emphysema, though this seems unlikely since they were all young men and in good health before being injured. This appearance was often associated with diminished movement of the diaphragm. It may be that some true traumatic emphysema results in these cases.

Penicillin as Chemotherapeutic Agent.—Chain and his associates point out that although in recent years interest in chemotherapeutic effects has been almost exclusively focused on the sulfanilamides and their derivatives there are other possibilities, notably those connected with naturally occurring substances. Following studies on lysozyme, it occurred to the authors that it would be profitable to investigate the chemical and biologic properties of the antibacterial substances produced by bacteria and molds. They began their studies with a substance produced by a mold in which Fleming in 1929 had observed antibacterial properties. Fleming noted that a mold produced a substance which inhibited the growth of staphylococci, streptococci, gonococci, meningococci and *Corynebacterium diphtheriae* but not of *Bacillus coli*, *Haemophilus influenzae*, *Salmonella typhi*, *Pseudomonas pyocyanea*, *Bacillus proteus* or *Vibrio cholerae*. He suggested its use as an inhibitor in the isolation of certain types of bacteria, especially *Haemophilus influenzae*. He also noted that the injection into animals of broth containing the substance, which he called "penicillin," was no more toxic than plain broth, and he suggested that the substance might be a useful antiseptic. The mold is believed to be closely related to *Penicillium notatum*. Methods have been devised for obtaining a considerable yield of penicillin and for rapid assay of its inhibitory power. From the culture medium a brown powder has been obtained which is freely soluble in water. It and its solution are stable for a considerable time and, though it is not a pure substance, its antibacterial activity is great. Various tests were done on mice, rats and cats. The tests made it clear that this substance possessed qualities which made it suitable for trial as a chemotherapeutic agent. Therapeutic tests were therefore done on mice infected with streptococci, staphylococci and *Clostridium septicum*. The general principle has been to keep up an inhibitory concentration of the substance in the tissues of the body throughout the period of treatment by repeated subcutaneous injections. The doses employed have been effective and not toxic; they may have been excessive. The solution contained 10 mg. per cubic centimeter of substance. In the first streptococcal experiment the treatment was continued for only twelve hours. That this was inadequate was shown by deaths occurring during the ten day period. In the second experiment the time of treatment was lengthened with improved results. In this and the two staphylococcal experiments, injections were given every three hours for the first

thirty-two or thirty-seven hours and then at longer intervals. In preliminary experiments with *Clostridium septicum* it was found that the infection could be satisfactorily held in check as long as penicillin was being given (that is, for two days) but that when the administration was stopped the infection developed. In another experiment the injections were given for ten days every three hours for forty-one hours and then at longer intervals, and twice daily for the last two days of the period. No deaths have subsequently occurred (twenty-two days after the beginning of the experiment). The results show that penicillin is active in vivo against at least three of the organisms inhibited in vitro. Penicillin is particularly active against the anaerobic organisms associated with gas gangrene.

Tuberculosis in Infants Under Three Months.—Ariztia traced the evolution of tuberculous infection in twenty-three infants under 3 months of age born of multiparous underprivileged mothers with advanced pulmonary tuberculosis, most of the mothers (nineteen) dying from tuberculosis within several weeks after delivery. Separation from the mothers at birth, feasible in a number of cases, did not act to prevent infection and death in all cases. An initially grave condition was almost invariably observed in those prematurely born, weighing generally less than 4½ pounds (2 Kg.) and presenting manifest indications of congenital debility together with high fever, enlargement of the spleen and liver, pyuria and regurgitations. Tuberculous were also observed occasionally. The author, however, calls particular attention to the cases which initially presented a complete absence of clinical symptoms but had a fatal anticlimax. Neither elevation of temperature, loss of body weight nor clinically observable objective signs occurred at first. The disease evolved slowly and deceptively, manifesting only a localized lesion which either did or did not become generalized. The symptoms appeared only shortly before a fatal termination.

The author emphasizes the diagnostic value of tuberculin tests and x-ray examinations. Tuberculin tests (Pirquet followed up by Mantoux, if Pirquet remained negative) were positive in all cases except two. In one of these only peritoneal tuberculous lesions were discovered at necropsy. The author believes that tuberculosis in infants under 3 months, born of tuberculous mothers, deserves greater attention as its course differs from that of older infants. Since the asymptomatic period is fraught with danger to the child's life, he advises the combined use of the diagnostic aids of tuberculin and x-rays without delay. In one case in which the child had been separated at birth from its mother and the pathologic condition had been positively established by tuberculin tests and x-ray examinations on the forty-fifth day, the symptoms, consisting in fever, loss of weight, splenomegaly and pyuria, did not manifest themselves until the end of the eighth week. Seventeen deaths occurred in the twenty-three cases reported. The type of lesions found is shown in a number of films.

*Insulin Lipodystrophy in Diabetic Children. M. L. Saldún de Rodríguez.—p. 642.

*Roger's Disease. B. Delgado Correa and O. Macció.—p. 652.

Insulin Lipodystrophy in Diabetic Children.—Saldún de Rodríguez reports three instances of lipodystrophy in children occurring in the course of the second or the third year of insulin therapy. This incidence occurred in a group of thirty-eight children with diabetes living under fairly satisfactory conditions of proper diet and insulin therapy. The insulin was administered in two or three daily doses of from 2 to 7 units for each injection, or in a daily total dose of 4 or 5 units. The injections were given in the external aspect of either thigh. The lipodystrophic lesions were symmetrical and located at the seat of injections in two cases and in the gluteal region in one case. The author believes that insulin lipodystrophy, either local or at a distance, is due to repeated injections of insulin in the same area in children predisposed to this condition from a disturbance of the nervous system. Injections of insulin make the region less sensitive to pain. For this reason the patient and the family ask the physician to give the injections in the same area. This practice must be maintained in order to prevent the occurrence of lipodystrophy.

Roger's Disease.—Delgado Correa and Macció found inter-ventricular communication of the pure form in forty-one of ninety cases of congenital heart disease. The condition was well tolerated and caused no functional disturbance. Coincidental with this abnormality, there was deaf-mutism in two, mongolism in two, facial asymmetry in one, thoracic abnormalities in three, rickets in three and muscular atrophy in one. Clinical diagnosis of the abnormality was made in thirty-five cases because of the presence of a loud systolic murmur audible over the cardiac area, especially at the left intercostal space, and which did not change in different positions. There was duplication of the second heart tone due to pulmonary hypertension in four cases, cyanosis in seven, dyspnea in eight, polyglobulia in one and precordial pain in one. The roentgenograms of the heart showed enlargement of the ventricles, which was unilateral in fourteen cases and bilateral in twenty-four. The electrocardiogram was normal in cases of inter-ventricular communication of the first and second degrees and showed either right or left ventricular preponderance in cases of inter-ventricular perforation of the third degree. A frequent abnormality was a deep Q wave in the third lead.

*Vitamin B₁ Content of Blood in Healthy Persons and Patients. S. J. E. Pannekoek-Westenburg and A. G. van Veen.—p. 1774.
Stimulation of Heart in Infectious Diseases. R. van Wesel.—p. 1785.

Vitamin B₁ Content of Blood.—Pannekoek-Westenburg and van Veen report studies on the vitamin B₁ content of 390 blood samples of healthy persons and of patients. The determinations were made by Meiklejohn's modification of Schopfer's test. This test estimates the amount of vitamin B₁ by means of its growth-promoting activity on the mucus *Phycomyces blakesleeanus*. The thiamine values of the blood of healthy natives

tallied with those mentioned in the European and American literature. The author regards 5.5 micrograms per hundred cubic centimeters of blood as the limit of B₁ deficiency. In six of the ninety healthy natives the thiamine content was 5.5 micrograms or less. The thiamine content of the blood of 165 patients with nutritional edema was on the whole like that of the healthy persons. Thus it seems probable that there is no relation between the nutritional edema and the thiamine level. However, among a group of twenty-two persons there were thirteen with low values; the fact that these patients had severe anemia with low cell counts is regarded as a possible explanation of the low values. Nineteen patients with manifest beriberi had divergent thiamine values; nine had low values, but some with severe beriberi had normal values. This may be explained by the fact that the patients may have had food with a high B₁ content or even B₁ tablets before they came for treatment, because the natives know the cause of beriberi. Of nineteen patients with polyneuritis of various origins all but two had a normal B₁ level. Of the two patients with low values, one had syphilis and one alcohol polyneuritis. The thiamine values of ten patients with tabes dorsalis was normal. On the basis of these observations the author concludes that the determination of vitamin B₁ in the blood is as yet of no great practical importance.

*Three Cases of Hyperinsulinism with Hypoglycemia Treated by Removal of Adenomas from the Pancreas. P. Windfeld.—p. 155.
Vascular Changes After Intravenous Injection of Thorium Dioxide. L. Efskind.—p. 177.

Hyperinsulinism Treated by Removal of Pancreatic Adenomas.—Windfeld presents histories of three patients observed at the Rigshospital in Copenhagen exhibiting hyperinsulinism caused by adenoma of the pancreas. All three patients had attacks of severe hypoglycemia which did not yield to dietetic treatment. Mental disturbances were prominent. The attacks occurred especially in the morning before the intake of food but also after physical exertion. Fatigue, lack of desire to work and depression predominate in the beginning, but later acute states of confusion, coma and clonic-tonic convulsions appear. Because the attacks resemble epilepsy, these patients are often sent to neurologic and psychiatric departments. Determination of the blood sugar during attacks will reveal the existence of hypoglycemia, and the subsidence of the attack on the ingestion of dextrose will confirm the diagnosis. Whipple emphasizes the following triad of symptoms to be found in all cases of hypoglycemia due to insuloma: (1) periodic nervous disturbances when fasting (2) in connection with hypoglycemia and (3) the favorable effect of the ingestion of dextrose. Whipple considers a case not amenable to surgical therapy if this triad is not present. Before operation is decided on, hypoglycemia from other causes (Addison's disease, Simmonds' disease, myxedema, hepatic disease and so on) must be ruled out. The author points out as especially characteristic the fact that patients with insuloma are nearly always fat in contrast to the thin or cachectic patients of adrenal or hypophyseal disorders. Detection of insuloma by roentgenography is almost never possible because of the small size of the tumors; their diameter rarely exceeds 2 cm. and they usually are embedded in the substance of the pancreas. Two of the patients had an adenoma the size of a hazel nut and of a cherry, respectively, in the head of the pancreas. The third patient had two adenomas the size of a large pea in the caudal portion of the pancreas. The author concludes that if attacks of hypoglycemia cannot be warded off by dietetic treatment an operation ought to be advised, for with protracted hypoglycemia irreversible changes gradually take place in the ganglions of the brain with persisting mental disturbances. Furthermore, about one in four of the insulomas removed have been malignant and exhibited a tendency to give rise to metastases.

The Physician Himself

PAUL D. WHITE, M.D.

BOSTON

There has been much ado in late years about the welfare, physical, mental and spiritual, of the butcher, the baker, the candlestick maker, the rich man, poor man, beggar man, thief, and even the lawyer and the Indian chief. The doctor, however, a vital factor in the campaigning for all these other souls, has been more or less left to look after himself, and, too much engrossed in the problem of helping others, he has too often neglected his own welfare. It is of some of the problems of the doctor, the noblest Roman of them all, that I would like to speak to you today.

Each one of us has his own body, mind and soul to look after but we often seek aid of others of our profession to advise us in all these fields, in fact, much more than we do of friends who are not doctors. In the course of talking with some 600 physicians who have been patients of mine and with the families of as many more, I have gradually become acquainted with some of the peculiar and unpeculiar problems that beset the doctor. This opportunity I have cherished more than any other in my work. Doubtless many of you, too, have had as rich or richer an experience but I hope that what I have to say may here and there bring helpful suggestions.

CARDIOVASCULAR DISEASE AMONG PHYSICIANS

The doctor's heart has become his own chief health concern. The frequency of cardiovascular disease among the physicians of the United States has in recent years been stressed annually in an editorial in THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION summarizing the causes of death in the American medical profession. In 1939 there were 3,710 deaths among about 175,000 doctors of medicine. The average age at death was 66 years, which might be worse but should be better. Heart disease was recorded as the cause of death in nearly half of the cases (1,585). Arteriosclerosis (453 cases), pneumonia (370), cerebral hemorrhage (368), cancer (357)

and nephritis (174) followed in that order. Diabetes mellitus claimed ninety-one, tuberculosis sixty and aneurysm five. If we include arteriosclerosis, cerebral hemorrhage and aneurysm and at least some of the cases of nephritis along with heart disease as cardiovascular disease, as of course we should do, then the total is very imposing (2,503 out of 3,710), far over 50 per cent, in fact a full two thirds. This is probably more or less the run of other professional men and in business, or perhaps a higher figure. The "cardiac" deaths have risen partly because of changes in customs of diagnostic nomenclature, partly because of greater accuracy and partly because other serious and earlier diseases (especially the infections) are on the wane. Then, too, of course there may be an actual increase. We can't tell yet. Certainly the doctor's life is a hard one and he doesn't have time or energy or initiative enough to lead a physically healthy life. He rarely can or does practice what he preaches. How much this fact has to do with the frequency with which he is hit by serious coronary disease is hard to tell; one may suspect that there is some sort of a connection.

It may be of interest to you to know what kinds of heart disease I have encountered among my own doctor patients, and some of my conclusions about them. Among the last hundred physicians whom I have examined because of symptoms or signs or suspicion of heart trouble, fifty-one had coronary disease with or without complications; only nine of these had hypertension; twenty-three had myocardial infarction without hypertension; ten had angina pectoris on effort only; one had rheumatic aortic regurgitation and angina pectoris, while the diagnosis in eight cases was based on clearcut electrocardiographic evidence alone (bundle branch block or abnormal T waves). Fourteen per cent of the group were hypertensive, nine having also coronary disease; one of the hypertensive patients had mitral stenosis. Third in the etiologic diagnostic list was rheumatic heart disease with 11 per cent; one of these patients had angina pectoris and

one was hypertensive. The commonest rheumatic valve lesion was aortic regurgitation, comprising 7 per cent of the total cardiac series, uncomplicated by mitral disease in 5; mitral stenosis was diagnosed in 4 per cent. Calcareous aortic stenosis was present in two cases and syphilitic aortitis with aortic regurgitation in one; no case of a saccular aortic aneurysm was encountered. Congenital heart disease (with auricular septal defect), subacute bacterial endocarditis, chronic cor pulmonale, acute cor pulmonale, thyrotoxicosis and "toxic" myocarditis were responsible for one case each. Pericarditis was present in two cases, one neoplastic and one unexplained. Eleven per cent of the patients were in congestive heart failure when I first saw them.

Thus, three fourths of the patients (76 per cent) were thought to have organic disease back of their heart trouble and yet there were a good many so-called functional disorders alone, and many more doctors have told me of or asked questions about their disorders of function (a kind of curbstone consultation) than ever came for examination. Among the hundred analyzed here four had uncomplicated extrasystoles, four had uncomplicated neurocirculatory asthenia (in seven others the neurocirculatory asthenia complicated other conditions); in three there was simply a cardiac neurosis, which in seven others was superimposed on something else; one had an unimportant functional murmur. One of the most interesting groups was that of three cases of auricular fibrillation with apparently normal hearts (two had resulted from excessive use of tobacco); in three other cases auricular fibrillation complicated heart disease. Of other arrhythmias paroxysmal tachycardia was found in four patients with organic heart disease, auriculoventricular heart block in three, and bundle branch block in five, an important finding ascertained only by electrocardiogram.

Eleven of this series of 100 patients had no heart trouble at all, either organic or functional, although they came as suspects. Two had gallstones instead, one had pleurisy, one a hiatus hernia, one a normal electrocardiographic variation, one a displacement of the heart to the left by old phthisis, one unexplained chest pain, one simple hypertension, and three others wholly normal hearts.

INDIVIDUAL PHYSICIANS WITH HEART DISEASE

I should now like to comment briefly on some individual "cardiac" doctors whom I have seen, to emphasize certain points of interest and importance. It is possible to be an excellent physician in good health after years of hard work and rich experience despite the presence of the acyanotic type of congenital heart disease, patency of the ductus arteriosus, for example, present in one of my colleagues. It is possible

to live with rheumatic valvular disease a long and useful life with no handicap to health therefrom and even without knowledge of the heart disease until nearly 80, as in the case of our own noted Dr. Herman F. Vickery, who showed at autopsy, after dying of pneumonia at 83, clear evidence of moderate mitral stenosis of rheumatic type. But unfortunately it is also possible to die in youth of acute rheumatic myocarditis superimposed on chronic rheumatic aortic valve disease, as happened to my friend George Reynolds last year, when while very tired he developed a streptococcic sore throat. I have found aortic stenosis of the calcareous type, quite possibly superimposed on old rheumatic valvular disease, in a few doctors, tolerated well for years but finally responsible for severe heart strain in later life. In one of these physicians a moderately loud precordial systolic murmur, causing rejection for insurance in middle age, was allowed to go unchecked after that in the rush of the doctor's life until abrupt left ventricular failure ten or twelve years later called attention to the classic evidence of aortic stenosis. I feel quite sure that annual physical examinations by a sensible colleague after the first discovery of the murmur could have revealed the enlarging heart and impending failure and have resulted in the postponement of disability by earlier reasonable regulation of life and earlier digitalis therapy. Some preventive medicine should certainly have been practiced in his case.

Another lesson I learned, and I suspect that we have all had to learn such a lesson, was in passing off as manifestations of fatigue and nervousness some palpitation and precordial and substernal aching in the case of a middle-aged doctor who showed no abnormality of the heart or aorta by physical examination, fluoroscopy or electrocardiogram but who, a year later, presented a very slight early diastolic murmur along the left sternal border and a positive Wassermann test. Had we bothered to determine his serologic reaction on the first examination we would have been a year ahead on treatment; fortunately he has now done well after three or four years of specific therapy.

A number of doctor friends have allowed themselves to get much too fat and, although a good many escape harmful consequences, only a few live to an advanced age and too many succumb to hypertension or coronary disease before they are old. I am thinking of one of my colleagues from the Smithfield ham and Lynnhaven oyster country who too tardily heeded the advice to reduce his weight and, although he lived a model life after his disability began, barely passed the age of 60, hypertensive coronary cardiovascular disease ending the story. It isn't always possible, of course, to be master of one's fate and the doctor has a peculiarly hard job in looking after himself;

but the utter neglect of their health by so many physicians is appallingly common.

In this connection I would cite one other case, that of a good doctor who had gradually from force of circumstances become responsible for the health of some 3,000 or more persons in a widespread community in Maine. He was on call day and night; the people could not get on without him. Apparently nobody thought it would ever be otherwise or that he was subject to human fatigue until one fine day, at too early an age, he was struck down by a crippling coronary thrombosis. I can't help but believe that his excessively difficult professional life with its perpetual wear and tear had something to do with his illness and that it would have been far wiser—in the long run, or even in the short run—had he secured one or two young assistants before the day he was forced to get them. Two advantages would have resulted had he done this: In the first place he would have conserved his own health and strength and, secondly, the adjustment of the medical care of the community at the time of his acute illness would have been far easier for every one concerned.

The lessons we have been learning about the prognosis of coronary thrombosis have come from our experience with doctor patients even more perhaps than from lay patients, but I still find physicians the most apprehensive and more in need of treatment for their loss of morale than for the heart lesion itself. Fortunately a more optimistic point of view is developing among the doctors themselves but there were a few, even years ago, who helped to steer their own destiny. One doctor in particular I will mention, much beloved in his own community and elsewhere, and known to many of you, the finest type of physician I have met. Nineteen years ago at the age of 60, in the midst of a very large family practice, he was hit by acute coronary thrombosis. He made a good recovery but realized that he must change his mode of life. Therefore he began the study of a special field, my own as a matter of fact, and in all the years since, in travel abroad and in clinics and courses in this country, he has kept abreast of the times, carrying on an active and important cardiovascular consulting practice in the state of Pennsylvania. Even after he was well past 70 he repeatedly came up to us in Boston and was of the most alert of our graduate students, an inspiring example for us all.

Increasing years frequently bring with them defects in the coronary circulation with symptoms therefrom but fortunately in many cases, perhaps in most, compensation occurs as the result of the development of an adequate collateral coronary blood flow. Over a period of such adjustment for weeks, months or even a year or two, caution in living is important; but

after the adjustment has been established a fairly normal life can often be resumed. The danger comes mostly from carelessness during the critical period. Only a relatively few persons are persistently severely crippled by coronary insufficiency over periods of years; too often a neurosis, neurocirculatory asthenia, bothersome arrhythmia or even an arthritis or bursitis accounts for much of the persistently recurrent symptoms which may start as angina pectoris and slowly change with the passage of time. Even the electrocardiogram may improve greatly in the course of time after acute or sub-acute coronary disease, and sometimes it may remain normal at advanced ages. A year or two ago I had the pleasure of seeing a normal electrocardiogram of a physician then in good health at the age of 105; he has since died suddenly and quietly at 106.

INTELLECTUAL ACTIVITY

So much for a few of the observations concerning physical health that have resulted from my experience with doctors as patients. I make bold now to comment on the doctor as an intellectual being. The physician from time immemorial has held a place as one of the leading citizens of his community and of his country, quite naturally so because he had in the first place to have the innate intelligence to be accepted as a scientific worker by preceptor or school and secondly because he passes through an arduous and prolonged course of instruction which must perforce sharpen his wits and cultivate his ability to make quick and sensible decisions.

"Knowledge comes but wisdom lingers" is a proverb particularly applicable to the doctor of medicine.

As long ago as the early days of the Greek era, the important position of the physician was recounted by Homer. During the siege of Troy, Hector at one time ran wild through the Greek army, and Paris, with his arrows, had wounded Machaon, who with Podalirius looked after the Greek sick and wounded.

The spouse of Helen, dealing darts around,
Had pierced Machaon with a distant wound.
In his right shoulder the broad shaft appear'd,
And trembling Greece for her physician fear'd.
To Nestor then Idomeneus begun:
"Glory of Greece, old Neleus' valiant son!
Ascend thy chariot, haste with speed away,
And great Machaon to the ships convey;
A wise physician skill'd our wounds to heal,
Is more than armies to the public weal."

Much later Plato quoted Socrates as saying to Euthydemus "Of course you who have so many books are going in for being a doctor." Not that a doctor was or need be bookish but his reputation has been that of having read widely and deeply, mostly of medicine of course, but largely in the lives of the many individuals, patients and colleagues with whom he comes

in contact. There need never be an idle moment in his intellectual life, any more than in his physical life. He has less time and need for problem plays and mystery stories and the gossip of the day than any other citizen in the community; his day is one long experience of the sort in his practice, in his teaching or in his research. His life is in fact so engrossing that, as I have said, he too often neglects his health and also too often fails to utilize or even to set aside a bit of leisure for a little intellectual diversion or avocation, no matter what it may be, something absorbing but not difficult, a mental refuge at frequent intervals during his active career, and one to which he may retire when his job is done. Such an avocation may be reading classical or modern fiction or history or biography, or even the writing of such, listening to music or practicing it, drama, painting, photography or modeling, collecting books or maps or anything else, or even dabbling in the fields of the other professions. Too often I have found that the physician who is ill, and must take weeks or months or even a year or two away from his work, faces a void—he must suddenly develop a hobby or avocation. There are some, however, who really welcome a respite, after the first shock of the discovery of their illness has passed, in order to do a few of the things set aside during the years that have passed for just such an occasion. There is only a slight danger that the avocation may prove to be more absorbing than the original profession itself, but if a man is gifted he may become a better novelist, sculptor or musician than he was a physician. There have been some notable examples of this. Care, however, must be exercised that a good physician should not step down to become a mediocre worker in some other field. Also it is true that a man cannot serve two masters: a physician cannot wisely spend the majority of his time on activities unrelated to medicine and expect to retain the confidence and patronage of sick persons, students and his medical colleagues.

THE SOUL OF THE PHYSICIAN

But it is the soul of the physician that puts him in a class by himself, in a place of honor the world around. May it never be tarnished! Temptations have always existed to convert the profession of medicine into a trade, and never more than now; but few have succumbed. Though inarticulate, the great majority of physicians have kept their virtue and have not yielded their birthright for a mess of pottage. For the last few years there has been unseemly quarreling about the danger and degree of state medicine. There has been raised the sad vision of the control of the profession by politicians, as of a football to be kicked about by whomsoever might be in the saddle. Fortunately the loud outcries are subsiding, and sanity and

dignity are returning even to those who have made the greatest fuss. Not that the practice and teaching of medicine do not need constant revision and correction like every other human endeavor, but such revision has been going on ever since Adam anyway and it helps but little, in fact it probably retards real progress, to call from the housetops how badly medicine is practiced, administered or taught in any community or state or nation. One can accomplish more by gentler methods, especially by personal example. The unselfish lives of most physicians are still the most potent argument in favor of their enduring need and usefulness. After all the smoke of the recent conflict has died away, we shall still be able to hail with humble satisfaction the words of Robert Louis Stevenson when he said:

There are men and classes of men that stand above the common herd: the soldier, the sailor, and the shepherd not infrequently; the artist rarely, rarer still the clergyman; the physician almost as a rule. He is the flower (such as it is) of our civilization; and when that stage of man is done with, and only to be marveled at in history, he will be thought to have shared as little as any in the defects of the period, and most notably to have exhibited the virtues of the race. Generosity he has, such as is possible to those who practice an art, never to those who drive a trade; discretion, tested by a hundred secrets; tact, tried in a thousand embarrassments; and, what are more important, Heracleian cheerfulness and courage. So that he brings air and cheer into the sickroom, and often enough, though not so often as he wishes, brings healing.

Finally, there is one other aspect of the spiritual value of the doctor. He should not only himself possess the highest ideals but should also have a voice in helping to elevate the moral and spiritual level of his own community and country, indeed of the world, and he should make it heard. Just because he is a busy physician does not mean that he cannot have or express opinions other than on health. In fact his altruism and honesty, which are virtues innate in his profession, make him especially fitted to combat, in every way he can, deceit, cruelty, barbarism and immorality wheresoever they exist, in high places or low. In these tragic days gangster régimes in the name of nationalism have professed and practiced these evils. Why should we doctors who abhor such things shut our eyes to them? Let us be honest and lend a hand toward the restoration of nobler things in this world of ours, not simply in our own little corner of the world. We are all neighbors now on old Mother Earth, and we American doctors can still stand for the liberty, honor and brotherhood of man, rejected by the mailed fist and at the moment more in need of help than are our physical ailments, which seem trifling in comparison. We must help to see to it that the night that is falling on the world does not last the threatened thousand years.

It is of interest in this connection that as long ago as 1902, nearly forty years back, William Osler wrote about nationalism as follows:

Nationalism has been the great curse of humanity. In no other shape has the Demon of Ignorance assumed more hideous proportions; to no other obsession do we yield ourselves more readily. For whom do the hosannas ring higher than for the successful butcher of tens of thousands of poor fellows who have been made to pass through the fire of this Moloch of nationalism? A vice of the blood, of the plasm rather, it runs riot in the race, and rages today as of yore in spite of the precepts of religion and the practice of democracy. Nor is there any hope of change; the pulpit is dumb, the press fans the flames, literature panders to it and the people love to have it so. Not that all aspects of nationalism are bad. Breathes there a man with soul so dead that it does not glow at the thought of what the men of his blood have done and

suffered to make his country what it is? There is room—plenty of room—for proper pride of land and birth. What I inveigh against is a cursed spirit of intolerance, conceived in distrust and bred in ignorance, that makes the mental attitude perennially antagonistic, even bitterly antagonistic to everything foreign, that subordinates everywhere the race to the nation, forgetting the higher claims of human brotherhood.

It is our profession, we physicians, who can do as much in the future as any other group, in fact probably more, in breaking the bonds of fettering nationalism, and after the bonds are broken in helping to restore the brotherhood of man. These are indeed high words and high ideals, but they constitute a natural evolution from our more ordinary care of man's body.

Massachusetts General Hospital.

Medical Students and the War

The *Lancet* has just published a Student's Guide,¹ although forced to curtail detailed information formerly published in its annual education number.

Medical students in England share the natural impulse to go with their contemporaries into the fighting forces, but they are advised to stay where they are because they will be of more use to their country as qualified medical officers. To settle down to the humdrum of studying and passing examinations requires character, particularly at this time, and not all of them can make the choice. More than one dean has written of students leaving to join up, of others who had to be restrained by advice, and of many who did not seek or did not heed advice in their haste to make a more active expression of service. Those who have remained have won the respect of their teachers by their anxiety to become qualified physicians as early as possible and so be available for any service which their country will require.

Nevertheless, the students have clamored for training and work which may be immediately useful. Some medical schools have arranged courses for training them for serving at first aid posts and on fire squads. Students have attended lectures and drills in their leisure and some of them have been directly responsible for the organization of first aid units. Every student at Oxford has been given a job in the Air Raid Precaution arrangements of the Radcliffe Infirmary, such as anesthetist, operation assistant, blood transfusion assistant or assistant in the mobile unit. Although the students naturally have wanted to join the Home Guard, in several schools the deans have felt that this service would require more of their time than they could well spare. In some places students have been encouraged to do farm work over

the week-ends. The women students who have trained as auxiliary nurses at the Municipal Hospital have done well a deserving war service.

The most serious problem at the medical schools has been to carry on the usual high standard of teaching with a depleted staff. The emergency plans have reduced the number of good teachers available, and it appears to some that the arrangements were made without due regard to the needs of medical education. A dean suggests that many of the teaching difficulties now present might have been avoided if a committee or person had been appointed to see that the work of the students was disturbed as little as possible for emergency measures. "The doctors of tomorrow" deserve the best that present conditions can provide.

Some of the present makeshifts in the medical schools are decidedly makeshifts, but others may be the seeds of a new kind of growth. Not all of the results of the upheaval have been disastrous. After a preliminary scattering of the teaching hospitals some have called their students home again to the parent hospital, some have planned a new curriculum which takes the students on a round of hospital visits, and some have stayed at home with a depleted teaching staff since the beginning of the war. Not many of the provincial medical schools have been evacuated, although all have plans to move if necessary.

In the London area the medical students have usually been distributed to two or three sector hospitals. It has been found that what one hospital lacks another can supply, and students like the increased clinical opportunities. Students of several medical schools have become residents in the sector hospitals where the teaching members of the staff are living. This return to the old hippocratic tradition of the teacher and pupil living in close fellowship is valued

1. Students Guide, *Lancet* 2:267 (Aug. 31) 1916.

by the students. This may be, it seems to some, the only significant innovation in medical education during the war years.

The *Lancet* reviews the changes that have been forced on many of the medical schools:

At Oxford since the outbreak of war the course has been modified to enable the student to take his whole medical course and to qualify as early as possible. The honors examination in physiology is being taken only by those whose tutors especially recommend them; others are being given a pass B.A. degree on the result of their first B.M. examination, thus shortening their course by a year. The medical schools of London were so much disorganized at the beginning of the war that Oxford University arranged for students to continue their clinical teaching at the Radcliffe Infirmary. Accommodation is limited and the number of entries will be restricted to fifty students a year.

The ranks of medical students at the University of Cambridge have been increased by men from St. Bartholomew's Hospital to whom the university has given hospitality. The number of students at Cambridge has not fallen off; on the contrary, it was considerably increased over that of the previous year. University life goes on as usual.

Most of the schools of the University of London moved out of London when war was declared, many of them becoming guests of universities in other parts of the country. Many of the medical schools have since returned to London. There have been no drastic changes in regulations or training in the University of London since the outbreak of war; no examinations were canceled, but the whole series of autumn examinations last year had to be readjusted. Students are received by the university after passing matriculation and become members of one of the thirteen recognized medical schools attached to the teaching hospitals. The students' union at the University of London has given up many of its activities; the boathouse has been requisitioned and the university air squadron closed down and was attached to the Royal Air Force station.

At St. Bartholomew's Hospital Medical School for the first three months of the war the medical students were scattered to eleven different hospitals, but by last January it was possible to arrange a course of medical study and to group the students in a limited number of hospitals. At present there are about 700 students in the medical college. The preclinical students of St. Bartholomew's have been working at Cambridge. The first year students taught by the St. Bartholomew's Hospital staff have been permitted to work in the laboratories of the Leys School. The clinical students have been housed in three hospitals, their first year of clinical work being done at Hill End, their second and half of the third year at Bart's, and the rest at Friern Hospital. The students at Bart's have formed themselves into bodies for various duties—stretcher bearing and dressing—and they work in close cooperation with the administrative staff. Resident experience is rather uneven at present; a man stationed on Hill End, for example, gets no outpatient work. Plans are under way to change the location of resident officers to give them a more general range of experience.

At the outbreak of war, Guy's Hospital Medical School found new premises at Tunbridge Wells, where four large buildings were equipped and furnished, some as lecture rooms and laboratories and others as dormitories. There are accommodations for 300 students. The remaining students live in lodgings in the district. The students in the clinical years are working either at Guy's Hospital itself or at the sector hospitals at Pembury and Farnborough. After a preliminary clinical period at Guy's Hospital the students

are sent to the sector hospitals for appointments as clerk and dresser, and after that they return to Guy's for the remainder of their training.

Medical education has been carried on satisfactorily at St. Thomas's Hospital in spite of a smaller number of patients and the loss of various members of the teaching staff to the defense services. The remaining members of the teaching staff have taken on extra burdens, but the spirit of understanding and good will from the students has prevented these from becoming too heavy. The students have worked keenly and well under conditions which make concentration difficult. The preclinical students were evacuated to Oxford at the outbreak of the war and enjoyed the hospitality of Oxford's laboratories for a time until the physiology and anatomy departments at St. Thomas's could be reopened. The teaching of gynecology has been hampered by the reduced number of cases, but the best possible use has been made of the material available. At present, with the exception of a few students who work at special hospitals in the sector, the whole St. Thomas's Medical School is centered on its normal base.

Charing Cross Medical School has 143 students, who at the beginning of the war were dispersed to hospitals in the sector and formal teaching ceased for three weeks. Last January the students were recalled to London from all the sector hospitals except one, and since then the school has returned almost to normal, although the number of patients in the hospital has been greatly reduced. The social and athletic activities of the students' club have been curtailed and their place taken by organized work done in spare time in all branches of the Air Raid Precautions, every student being trained in first aid, stretcher bearing, fire fighting, and anti-gas measures.

For the first term of the war, preclinical students at Middlesex Hospital Medical School were sent to Bristol University. They were recalled last January and have been at work at Middlesex ever since, except for about sixty students who are still distributed in three sector hospitals. The preclinical students have been trained in Air Raid Precautions, especially fire fighting and anti-gas measures, and are available to act as runners. At present there are about 320 students at Middlesex Hospital.

Medical education at the University of Liverpool has been normal in the last year except for adjustments to meet Air Raid Precaution regulations. To expedite the training of students so they can serve as assistants in the wards as soon as possible, all academic and clinical courses have been brought forward by a turn, and the times at which resident house posts become vacant have been adjusted so that they correspond with the final examinations; thus the students may become resident officers immediately on qualifying. Social activities at the University of Liverpool have been little affected; the debating society meets each week and there have been as usual two dances, a ball and a dinner.

At the outbreak of the war the wards of the Cardiff Royal Infirmary, which is the chief hospital of the University of Wales School of Medicine, were almost emptied in preparation for war raid casualties, but after a month it was possible to fill the beds in the wards again with the customary types of patients; so far teaching has proceeded normally, although some teachers have joined the defense forces.

The University of Wales has received fifty clinical students from a medical school in London, in addition to its own students, and to accommodate them a drill hall adjacent to the school was hired for the teaching of pathology.

At the University of Edinburgh the medical course has been carried out during the past year on much the same lines as usual, although students in addition to

the usual courses have received special training in first aid, the treatment of air casualties and gas injuries. It has not yet been necessary to distribute the medical school to other quarters, but plans have been made if it becomes necessary.

It has been possible to continue medical teaching on normal lines at the University of Glasgow, where at present there are 1,170 students; laboratory work had to be modified for a while owing to the blackout. During the year the University of Glasgow has received 180 anatomy and physiology students with their teaching staff from Kings College, London.

Owing to the continued neutrality of Ireland, medical education at the University of Dublin has been little affected by the war and at present there are 465 students. Teaching in the ten clinical hospitals at Dublin also has not been materially influenced by the war.

At Kings College Hospital Medical School, for the first four months of war, teaching was carried on at several centers in the sector to which the medical students had been distributed, but since last January the work has been concentrated in Kings College Hospital itself, Horton Hospital at Epsom, and the Blind School Hospital at Leatherhead. However, the anatomy and physiology students from King's College were sent to the University of Glasgow. Students working in the sector hospitals accommodating Kings College Hospital Medical School live either in billets nearby or in the hospitals themselves. They find that the work in the several hospitals gives them a wider outlook than a fixed course in one hospital, but they get no experience with outpatients in the sector hospitals and they are cut off from laboratories, libraries and

museums. Kings College, however, has overcome these difficulties to some extent by sending books and pathologic specimens out to the sector hospitals.

The *Lancet* summarizes the situation in the other medical schools in Great Britain. In general, medical students in the London area have usually been distributed to several sector hospitals. While the fixed courses and routine of the student's existence have been greatly upset, this shoving and changing, the *Lancet* says, has proved stimulating rather than unsettling. The students like the increased clinical opportunities and there have been plenty of patients even if they have to be hunted out of scattered lairs. Few of the provincial medical schools have been evacuated, although all of them have made plans to move if necessary.

The dean of St. Thomas's sees lessons for the future in the present arrangements. The preliminary medical subjects and anatomy, he thinks, might well be taught in two or three large centers. The teaching of physiology, he says, should inform the whole medical course and should not be tucked away in a watertight compartment. He also sees in the future a curriculum no longer loaded with deadwood, and a more rational allotment of time in the various phases of training.

Digests and Reviews

"TWENTY-FIVE YEARS"

The School of Medicine of Washington University and affiliated hospitals in St. Louis has just published a beautiful booklet dedicated to the twenty-five years of training medical students and nurses and of caring for the sick since the hospital and medical group were constructed in the present location on Kingshighway adjoining Forest Park. Following the well known survey of medical schools by the American Medical Association and the report by Abraham Flexner for the Carnegie Foundation on medical education, the medical department of Washington University was reorganized with new hospital affiliations, and the new buildings constructed were dedicated in April 1915. The booklet reviews the history of the medical school from its beginning. The great task of finding those who would financially support the building of a great medical school with affiliated hospitals was guided by Robert Somers Brookings, who was president of the corporation at that time and who not only threw his own fortune and enthusiasm into this work but was able to obtain great sums from families, foundations and other sources.

The greatness of this institution is illustrated in the panoramic view of the campus on the cover of the booklet, in which grateful apprecia-

tion of the numerous gifts which provided these facilities and supported the multitude of activities that have been carried on in them throughout the twenty-five years is expressed. The three original laboratory buildings and much of their original equipment were given by Mr. Brookings, to whose vision the medical center stands as a monument. The names of Edward Mallinckrodt, Elisa McMillan and Oscar Johnson also are deeply engraved on this monument. Hundreds of others have contributed in proportion to their means to this enterprise, and still others have given in service and time a devotion that money could not buy. Beside individuals, several foundations have generously aided in the development and operation of the medical school. The General Education Board and the Rockefeller Foundation have given university endowments of more than \$6,000,000, the income of which mainly supports the clinical departments. The Commonwealth Fund, the International Cancer Foundation and the Markle Foundation have given generously to term grants to support research projects in hospitals and laboratories. Nevertheless the decline in yield from endowments in recent years has been great, and at present no department in the medical center has a budget large enough to meet its urgent needs, and the resources of the school are not sufficient to maintain the activities at

present levels or to permit new undertakings and improvements essential to normal growth. The most urgent need at present is for unrestricted funds to replace this loss, so that the essential activities can be maintained on a high level. Some of the particular needs of the school are discussed in this booklet.

No recital of figures or money spent or patients treated or students trained would serve to express the service rendered to the sick and the contributions to medical science made from these institutions, the members of the staff of which have included many of the foremost men in medical science.

Here one finds brief mention of some of the contributions to medicine. The first successful removal of a whole lung for cancer was performed in these hospitals, an operation now performed throughout the world. Surgeons from distant countries have come to this medical center for special training. The site of formation of the principal female sex hormone was first established in the laboratories of this medical school. The work begun here led to the isolation of this hormone by others in other universities, thereby establishing a cornerstone of the new science of endocrinology. Another member of the staff has to his credit the first isolation (elsewhere) of progesterone. Insulin, the hormone of the pancreas, is said to have been first isolated in pure form in these laboratories by methods since utilized in its commercial production. A technic which renders the gallbladder opaque to x-rays and therefore visible on the x-ray film, which was developed in this medical center, has greatly increased the accuracy of the diagnosis of gallbladder disease. Virtually every member of the staff conducts some form of investigation, and of the thousands of papers published from departments of the medical school during the twenty-five years some represent notable contributions which have made the authors eminent.

During the first quarter century of operation, 1,791 medical students from nearly every state in the union have been graduated from the medical school, 625 graduates have been trained as house officers in the affiliated hospitals, and 810 student nurses have graduated from the school of nursing. Twenty-five years ago the entering class of medical students was reduced to fourteen in consequence of the stricter admission requirements, but this number has increased gradually until in 1930 the present limit of eighty-two was reached. The number of applicants to enter the medical school at present is about ten times the number accepted, and the selection of the best qualified candidate is a difficult task. The medical school, however, has scholarships which make it possible to accept a few students of unusual ability and promise who without its aid would be unable

to study medicine. Loan funds are available to tide worthy students over periods of financial emergency, and last year scholarships amounting to \$12,000 and loans totaling nearly \$3,000 were awarded.

Last year more than 41,000 were treated in these hospital clinics. The 2,545 living graduates of the school of medicine and of the schools from which they sprang are engaged in practice and teaching throughout the world, and of the six continents only South America and Australia have no representatives in this medical school.

Among the numerous pictures in the booklet are those of members of the faculty twenty-five years ago who still continue in that capacity.

The booklet not only reviews the development of this great cooperative enterprise and its progress throughout the last quarter century but expresses the outlook in facing future opportunities to serve this community and to aid in promoting the health of mankind.

THE PLACE OF PATHOLOGY AMONG THE MEDICAL SCIENCES

Condensed from the First Kettle Lecture, by W. W. C. Topley, published in the Lancet, Dec. 3, 1938.

A scientific territory has no natural frontiers. Its borders are nebulous and changing. It may expand rapidly in one area and sometimes contract in another, and wherever it touches a neighboring field of work there is a mutual infiltration.

A growing science not only expands: it buds and divides. Physiology and pathology are offshoots of medicine. Pathology, in response to the stimulus provided by Pasteur and by Koch, has branched into medical bacteriology, and both physiology and pathology have united with chemistry to produce offspring that have demanded names of their own.

In each of the biologic sciences there has been a general drift from a systematic study of structure and relationships to a study of function, and from a study of any given function as an integrated whole to an analysis of the mechanisms on which that function depends. The movement is, of course, only a shift in the immediate focus of intellectual interest and effort.

Although this drift has been general and continuous in direction, it has not been continuous in rate; so that it is possible to ascribe to particular periods, and often to particular persons, an acceleration so striking as to constitute a new epoch in the branch of the science concerned.

Pathology, like physiology, began with a study of structural changes; but it was still in this phase when physiology had undergone its metamorphosis into an experimental science.

It does not follow that pathology is morbid anatomy or that morbid anatomists are the only

pathologists. A pathologist must have some knowledge of structural tissue changes, but he must also know enough physiology to relate abnormal structure to abnormal function, enough biochemistry to understand something of the chemical causes, or consequences, of the pathologic processes that he studies, and enough bacteriology and immunology to give him some insight into the mechanisms involved in infective disease. No man can be a master in each of all these fields; but they are all pathology, and none of them have an exclusive right to that title.

RELATION BETWEEN MORBID ANATOMY AND BACTERIOLOGY

If the common use of the label pathology as a synonym for morbid anatomy is misleading, the label bacteriology, as far as it implies a differentiation from pathology, is more misleading. The bacteriologist, properly so called, is clearly a particular kind of botanist. He studies bacteria as such. The medical bacteriologist, on the other hand, is a pathologist who is concerned with bacterial and virus infections of man and animals. He must spend much of his time and energy in studying the parasites; but he cannot neglect the hosts. The tissue changes associated with infection are clearly within his province.

A considerable part of the pathologist's work is still concerned with the observation of naturally occurring events not subject to experimental control. He has, therefore, to guard carefully against drawing premature conclusions from inadequate data, and rapid solutions are unlikely to come his way. What is less often realized is that he usually suffers from a similar disadvantage when he confines himself to the experimental field. Here, I think, there is a sharp contrast with physiology. It would not be a gross misrepresentation to attribute the rapid advance of physiology in the last half-century to the successful designing and exploitation of acute experiments—acute, I mean, in point of time. By his skill in this direction the physiologist has been able to obtain rapid answers to many of his problems, not only because experiments of this type give their answers quickly but because their very shortness of duration helps to eliminate the chance intrusion of many disturbing factors. It is altogether probable that similar methods will yield valuable results to the pathologist when he is in a position to use them, and one of the hopeful signs of the present day is the entry into the pathologic technic; but for a long time to come pathologists will be largely concerned with experiments that are as chronic as the processes they are designed to study, and the technic of the long term experiment will be an essential element in their training.

CATEGORIES OF SCIENTIFIC RESEARCH

Scientific research can be roughly divided into two broad categories: those inquiries that are determined mainly by the nature of the problem to be solved and those that are determined mainly by the nature of the technic to be employed. The great names and the great moments of science are associated with a transient merging of these two categories. A technic developed in an attack on one particular problem is found to be applicable to a multitude of related problems, all of which are pressing for solution. Such a period occurred in the bacteriologic field between 1880 and 1900, when, as Löffler put it, "Koch shook the trees and the apples fell." But it is seldom long before the advent of the period of diminishing returns. The new technic takes its place as one of the tools of science, but the advance on that particular front slows up until some new technic is invented. There are not many Pasteurs or Kochs, and the efficacy, even of these great ones, depends in part on the times in which they live and on developments in other branches of science that provide them with the instruments that they exploit. At most times, and for most of us, the choice is less happy. We can attack a chosen problem by slow and relatively ineffective methods, developing them a little where we can, or we can select a technic and apply it to such problems as it is clearly fitted to solve. There must always be compromise based on judgment and experience. The wise investigator will not attack a problem, however interesting or important it may be, if he sees no hope of solving it; nor will he, except when he is learning his trade, be content to apply some existing technic to a trivial problem merely for the sake of getting an answer that can be put on record.

Avoiding these extremes, the choice is free. We need both types of work; and, if we need them it is well to appreciate and understand them. There is, I think, a danger of judging too much on results, and particularly on the form in which results can be presented. The neat and tidy answer to one problem may represent no more significant advance than the ragged and partial solution of another. Above all, it is a frank misuse of words to suggest that the one result is more "scientific" than the others or has been gained by more "scientific" means. So long as the canons of working hypothesis, experiment and deduction are properly observed, and dubious conclusions from inadequate data are avoided, there is no reproach in facing the difficulties of a long road where no short road is available.

RELATION OF PATHOLOGY TO CLINICAL MEDICINE

Neither pathology nor physiology can ignore the problems of clinical medicine, though individual pathologists or physiologists may be well

advised to do so. The clinician, on his side, cannot ignore pathology and physiology. As a result of our labeling, and of the academic organization that has arisen out of it, boundaries have been erected that involve not only separate professional chairs and readerships but separate institutes. Some such separation was inevitable, if only for administrative purposes; but it is worth while to ask two questions: Does it matter? If so, can we do anything to neutralize it?

The answer to the first question, so far as research is concerned, is that for the really original worker, the man who will do the biggest things, it does not matter at all. He will find the niche that suits him, and if he wants help from others, or knowledge that lies outside his immediate sphere of activity, he will get it in one way or another. For the ordinary man I think it matters much more. I do not, for instance, think it is good for a young pathologist in his early or middle twenties to be labeled a morbid anatomist or a bacteriologist or a pathologic chemist and run in blinkers from that day onward. If he is to go far he may, in the long run, have to be mainly one of these things, but a more general background, acquired by some years of browsing in a wider field, is far more likely to put him on a fruitful and congenial line. He will, for one thing, be able to wander in the borderlands, and borderlands are profitable places to explore.

From the point of view of the application of physiologic or pathologic knowledge to curative or preventive medicine I believe that the existing separation matters profoundly. It is the main reason why medical practice and medical science fail to advance as quickly as they might. If the present separation of the medical sciences is harmful, can we do anything about it? I think we can.

INFILTRATION AND INTEGRATION IN MEDICAL EDUCATION

The crux is clearly education. I know of no other curriculum which is so frankly a system of almost disconnected examinational hedges to be jumped and forgotten. The student does not carry much chemistry or physics into his two years of anatomy and physiology. When he starts clinical work he is sometimes told quite frankly by the surgeon that he can forget most of his anatomy and, by the physician, that he can forget most of his physiology. If he fails to be told this in explicit terms, he deduces it himself from the fact that he hears little more of these subjects. By this time, of course, he needs no telling to forget his chemistry and physics. He has done that long ago.

With pathology, in its wide sense, the case is not so bad, for its study extends well into the clinical years; but it is bad enough. The

real test of a satisfactory education in medicine is that it should, at one and the same time, fit the student for the work he is going to do in life and teach him to understand and apply the principles on which all true scientific work is based.

Much could be done by a system of infiltration, and in this infiltration I think that pathology, in the broad sense, has an essential part to play.

We should introduce the concept of disease processes, of abnormal function and structure, much earlier and continue the teaching of the ancillary sciences much later in the medical curriculum. This would mean the scrapping of certain things that are now taught, but I would willingly let them go. If the student knows well those parts of anatomy, physiology and pathology that have a direct bearing on his clinical work—knows them so that he can grasp their significance and can discuss them intelligently—he will be a better scientist and a better clinician than if his heritage from his preclinical studies is a vague recollection of a partially digested mass of unappreciated facts and theories.

Apart from the thorny question of medical education, there are other things that we can do if our general aim is to break down existing barriers and build as few new ones as is possible. Separate chairs of morbid anatomy, bacteriology and pathologic chemistry have become an obvious administrative necessity; but I mistrust the housing of this family of sciences in different buildings, nor would I give to one more than another the right to adopt the family name of pathologist.

We shall do well to encourage men whose early training has been in one scientific field to migrate to another and to look favorably on a shift of subject matter from one departmental territory to another. As subjects grow and their technical methods extend or change, there are many problems that are best dealt with in departments other than those in which they first arose. Bacterial enzyme systems, for instance, are clearly the concern of the biochemist rather than of the bacteriologist. We should, at least, be wise not to take out patent rights in any subject but to welcome to adoption even of our pet problems by any one who is prepared to treat them intelligently.

In pathology, the establishment of research institutes and of diagnostic laboratories, in addition to university and hospital departments, is tending to separate three functional classes—the research worker, the applied or so-called clinical pathologist and the teacher. Kettle would, I think, have endorsed the view that most pathologic investigators are the better for a period, if only a short one, spent in diagnostic work, and that the routine worker profits greatly

by an opportunity to attack some of his problems as ends in themselves.

I believe that freer movement across these functional barriers would solve many of our difficulties. Some men will do their best work as investigators, some as teachers and some in applying their laboratory technic to clinical or public health problems. But it is not always clear at the start where a man's gifts lie, and a change of work and experience, a few years' teaching for the research worker, a few years' continuous research for the teacher, and so on, would keep open paths that are closed by premature limitation to one field of activity.

In addition to trying to abolish barriers that already exist, we must prevent the erection of new ones. For example, clinical science, which bears the same general relation to clinical practice that academic bears to applied pathology, is rapidly developing along lines of its own. This movement is perhaps the most important and the most hopeful of the many signs that the medical sciences are developing—that elusive entity known as a Group Mind. It is not altogether fanciful to note the growing evidence that the individual mind, for its healthy functioning, depends much less than we had supposed on localized and specialized areas of activity, and much more on the effective integration of cerebral activity as a whole. To insure such integration in the growing mind of medicine, we must insure that the morbid anatomist, bacteriologist or biochemist who works for the time being in a department of clinical science is not separated in any way from his colleagues who work in the departments that are labeled morbid anatomy, bacteriology or biochemistry.

No man can compass the range of the medical sciences; but we can develop a common tradition, a common background of knowledge and a common way of thought. We can do this best by breaking down existing barriers and erecting no new ones and by training those who

come after us to respect scientific method, which includes accurate and critical observation, rather than to acquire, and then forget, an arbitrary collection of unrelated facts and theories.

Pathology, in the course of its development, has faced its own problems and devised its own ways of solving them; but we shall best serve medicine, and ourselves, by not stressing too strongly the particular technical methods on which we have relied in the past, and by a willingness to discard labels or disregard them. If institutes of pathology housed workers who would, under our present conventions, be regarded as physiologists, pharmacologists or biochemists, as well as morbid anatomists and bacteriologists, and if to these could be added others whose usual label would be clinicians, we should not only increase the value of the work done in these institutes but provide the personal links that alone make possible effective cooperation. To be fully effective there would have to be free interchange. It would become a matter of temporary convenience whether a man worked in the department of physiology or the department of pathology, or whether another chose, for the moment, to regard himself as a bacteriologist or a biochemist. It would be essential that there should be no prescriptive rights to senior posts, that a man should not, because he chose to wander between two or more departments, be debarred from normal promotion to any one of them.

There is one factor on which the success of all such dreams depends, and that is the personal one. Cooperation can never be forced, though it can be encouraged. In Kettle's death we lost one who had the gift of true cooperation at its best. His last years were spent in laying the foundations of the department of pathology of the British Postgraduate Medical School, and in his last few days he was thinking of its interests.

Comments

Twenty-two years ago in the worldwide pandemic of influenza there were more than 200,000,000 cases, and upward of 10,000,000 deaths occurred in less than twelve months. In the United States alone there were more than 20,000,000 cases and about 450,000 deaths in less than six months.

Dr. John Lambert Richmond was the first surgeon in the United States to perform a successful cesarean section. The operation was done in Middletown, Ohio, in 1827, without adequate assistance, with only a small pocket case

of instruments by the aid of candlelight. The mother survived, but the child died. Dr. Richmond graduated from Ohio Medical College in 1822.

The first operation for gallstones was performed by Dr. John Stough Bobbs of Indianapolis, June 15, 1867. The patient survived and lived for many years afterward. The operation was performed in an upstairs room in a business block. Dr. Bobbs was one of the leading surgeons in Indiana of his day and was the first professor of surgery in the old Indiana Medical College, organized in 1869.

Medical College News

Medical schools, hospitals and individuals will confer a favor by sending to these headquarters original contributions, reviews and news items for consideration for publication in the Student Section.

Clinical Work for Jefferson Juniors

The students of the junior class at Jefferson Medical College, Philadelphia, this year are following a new schedule made up of fewer didactic lectures and more clinical work. The clinical clerkships in the departments of medicine, surgery, pediatrics, dermatology, otology, laryngology, genito-urinary surgery and physical therapy consist of groups of eleven students in a section in attendance on patients of the Curtis Clinic, which is the outpatient department of Jefferson Medical College Hospital. The junior class numbers 130 members, including fourteen students from Alabama, North Carolina, Dartmouth, Wake Forest and Missouri.

Cornell Students Elect Military Training

Training in military medicine has been elected by almost half of the student body of Cornell University Medical College, New York, where courses in the subject are being offered to all four classes, the college announces.

Of the 274 male students, 113 are taking military training and will be eligible on graduation for commissions as first lieutenants in the Medical Reserve Corps.

Designed to provide the army with trained, young, medical personnel, similar courses are being given in about thirty selected medical colleges throughout the country, Cornell being the designated place of study for New York. Dr. Philip B. Connolly, Lieutenant Colonel, U. S. Army, retired, has been detailed by the war department to direct the study here.

Supplementing the college's regular medical curriculum, the courses cover the principles of military science, first aid, treatment of war wounds, camp and field sanitation, preventive medicine as it relates to the diseases common to armies, and related subjects. In addition to didactic instruction and demonstrations, a six weeks camp is held at Carlisle Barracks, Pa., at the end of the second or third year.

Alien Students Must Register

The Department of Justice recently issued a statement cautioning the 6,000 alien students now in this country that they must be registered and fingerprinted before December 26. Because they have been admitted under a special non-quota classification, alien students must present acceptance credentials from a school or college approved by the student division of the Immigration and Naturalization Service, which supervises their activities after admittance. Non-quota alien students are required to carry at least twelve semester hours of academic work, and they must be 15 years of age or older at the time of their admission. The average age of alien students now in the United States is 18. The largest group of alien students in this country today is at Montezuma Seminary, Montezuma, N. M., where 330 students from Central and South American countries are enrolled. These students have been coming to this country since 1937 instead of attending seminaries in Rome and other European cities. The second largest group of alien students (280) is at the University of Michigan; the third (260), at Columbia University; the fourth (175), at the University of California; Harvard, Massachusetts Institute of Technology and the University of Chicago each have 100 or more.

Aviation Medicine at Virginia

The University of Virginia School of Medicine, Charlottesville, is offering a course in aviation medicine this year, including lectures sponsored by the U. S. Army Air Corps and given by a medical officer of the army, and lectures in the departments of physiology, otolaryngology and cardiology. This, it is said, is the first medical school in the country to offer a course in aviation medicine.

Harvard's National Scholarships

Harvard University, Cambridge, Mass., announced, October 11, the award of National Scholarships, the outstanding awards to students entering Harvard Medical School this fall, to James S. Clarke, LaGrange, Ill., S.B., Harvard '40; Martin E. Flipse Jr., Douglaston, L. I., N. Y., A.B., Hope College '40, and Winsor C. Schmidt of Rye, N. Y., who attended Yale. Winners of the scholarships who maintained honor records continue to hold the awards until graduation. The holders of National Scholarships now in the medical school are: Louis E. Ward '43, Mount Vernon, Ill.; Allan L. Friedlich Jr. '43, New York; Glen R. Leymaster '42, Aurora, Neb.; Clarke T. Case '42, Pymmana, India; Laurence G. Wesson Jr. '42, Boston; Ward S. Fowler '41, Eldora, Idaho; Carl C. Gardner Jr. '41, Columbia, Tenn., and William F. Loomis '41, Tuxedo Park, N. Y.

West Virginia Sophomores Honor Freshmen

The sophomore class of West Virginia School of Medicine, Morgantown, held its nineteenth annual "mix," honoring the freshman class, September 18, at Newman Hall, and nearly all the members of the faculty and student body were present. Refreshments were served. Dean Edward J. Van Liere welcomed the new students, as did Robb S. Spray, Ph.D., professor of bacteriology and public hygiene, and Dr. Simon B. Chandler, professor of anatomy and neurology. During the summer the medical school buildings were redecorated throughout, and several new microscopes were added to the department of bacteriology and pathology.

Western Reserve Changes Curriculum

The medical school of Western Reserve University has decided to substitute required additional work in biochemistry, biostatistics, medical psychology, physiology, pathology and immunology for the optional work in the first year and several optional courses in the second year. Experience indicates that this is advisable to insure a sufficient knowledge of fundamental subjects. Neuro-anatomy will be moved from the second year to the first year. The total number of required hours is increased from 850 to 1,017 in the first year and reduced from 904 to 864 in the second year.

California Visitors

The University of California Medical School, San Francisco, and the laboratories of the Division of Biochemistry in Berkeley recently had the pleasure of visits from Dr. Arthur J. Walker of Freetown, Sierra Leone, South Africa; Dr. George W. McCoy of the U. S. Public Health Service; Dr. Andrew W. Sellards of Harvard Medical School, Boston; Dr. Karl Menninger, Topeka, Kan., who delivered an address before

the California Academy of Medicine in San Francisco; Dr. Philip C. Jeans, professor of pediatrics, State University of Iowa College of Medicine, Iowa City, following a trip to Los Angeles, where he had given a series of clinics; Dr. Clinton H. Thienes, professor of pharmacology, University of Southern California School of Medicine, Los Angeles; William A. Perlzweig, Ph.D., professor of biochemistry at Duke University School of Medicine, Durham, N. C.; R. J. Cowan of the Institute of Medicine and Veterinary Science of Adelaide, South Australia, and A. J. Llacer and J. C. Sozzi, who completed two months' study in ultramicrochemical analysis in Berkeley.

"Living High" at Northwestern

Eighty medical students of Northwestern University Medical School, Chicago, live on the sixth, seventh, eighth and ninth floors of the new twenty story student dormitory on the lake front at Huron Street, which is believed to be the tallest building in the

Abbott Hall

world used exclusively as a university dormitory. The new skyscraper is named Abbott Hall for Wallace C. Abbott, founder of Abbott Laboratories, and his wife, Clara A. Abbott, from whose estate Northwestern University received a gift of \$1,500,000 for use in medical, chemical and surgical research. Abbott Hall accommodates a total of 850 students on the Chicago campus of Northwestern, where the professional schools and the evening departments are located. Abbott Hall is Gothic in style, built of Indiana limestone, and each residential floor accommodates fifty-six students. The arrangements permit members of the fifteen fraternities, which previously had occupied temporary residences off the campus, to have a floor or part of a floor for their exclusive use. In the building are shops, libraries, dining rooms, lounges, squash courts, bowling alleys and a recreational roof garden. Across Lake Shore Drive, which the dormitory faces, is a new beach on Lake Michigan.

University of Georgia

The students and faculty at the University of Georgia School of Medicine, Augusta, joined in a social get-together, September 18, which was one of a series of meetings sponsored by the student-faculty council to promote a spirit of fellowship and cooperation.—A new hospital building, costing \$100,000, is to be constructed on the campus through the generosity of Judge S. Price Gilbert in memory of his father, Dr. Jasper Newton Gilbert, who graduated from the medical school in 1835.—Work has been completed on the improvements to the medical school library, made possible by a grant of \$10,000 from the Rockefeller Foundation and \$15,000 from an anonymous donor.

The Inaugural Session at Jefferson

Dr. Hobart A. Reimann gave the introductory lecture at the opening of the 116th annual session of Jefferson Medical College of Philadelphia, September 18. Dr. Reimann's subject was "Education of the Medical Student." The total enrolment at Jefferson this year is 513, of which 133 are members of the freshman class. All the freshmen completed four years of college work before they were admitted to Jefferson. They came from seventy-five different institutions from twenty-nine states, insular possessions and foreign countries, including Brazil, Korea, Iran, Puerto Rico and Hawaii.

Summer Clinic Service for Creighton Seniors

Creighton University School of Medicine, Omaha, inaugurated this year a summer clinic service for sections of the senior class, alternate thirds of the class spending about seven weeks of the summer in the clinic. The service proved highly satisfactory from the point of view of both students and teachers, and next summer it will be tentatively extended to the incoming junior students. Being relieved of didactic work during this period, the summer clinic service permitted the seniors to study each case more fully.

Medical History at Tulane

Charles W. Crumpton, sophomore at the Tulane University of Louisiana School of Medicine, New Orleans, was awarded the Rudolph Matas prize for the best paper on history of medicine at the annual banquet of the History of Medicine Society, May 15. Mr. Crumpton's paper was on Sir William Osler. Gilcin F. Meadors Jr., '40, was awarded the I. I. Lemann prize for his paper on Marion Sims.

Death of Dr. John McCrae

In the Student Section, September 28, it was said that Dr. John McCrae, Montreal, Canada, author of the poem "In Flanders' Fields," was killed in service during the first World War. It has been learned that Dr. McCrae died of pneumonia. J. C. Simpson, LL.D., the dean of McGill University Faculty of Medicine, Montreal, where Dr. McCrae was a member of the faculty, writes: "In the winter of 1917-1918 Lieutenant-Colonel McCrae was in charge of medicine in No. 3 General Hospital (McGill), C. E. F. at Boulogne. On the evening of January 23, word was received from headquarters that he had been appointed consulting physician to the First British Army Corps. The officer commanding his unit went to Colonel McCrae's quarters to offer congratulations but found him with a temperature around 99 F. and persuaded him to remain in bed till morning. The next afternoon definite signs of pneumonia began to develop and he was transferred next day to No. 14 British General Hospital for Officers. He rapidly sank, however, and died at 1:30 o'clock in the morning of Jan. 28, 1918."

Prizes Awarded at Temple

At the annual dinner of the graduating class and the medical alumni association of Temple University School of Medicine, Philadelphia, June 12, Dean William N. Parkinson awarded the following prizes to graduates and students for 1940:

Maurice L. Brown, the faculty prize, a gold medal for having attained the highest average during the four years course; the gynecology prize by Professor Hammond to the senior with the best record at the end of the course in gynecology; the proctology prize by Professor Hibshman to the senior for the best examination in proctology.

Clarence A. Holland, the alumni prize of \$25 to the senior passing the best examination for the year, provided the last three years of the course were taken at Temple.

Harold V. Harbold, the surgery prize by Professor Babcock to the senior giving the best written report of the surgical clinics for the year—a gold medal and \$50; the second prize, a silver medal and \$25, was given to Clarence A. Holland.

Gilbert Barron, the rhinology prize by Professor Ridpath to the senior passing the best examination in rhinology.

Robert J. Jahn, the otology prize by Professor Ersner to the senior passing the best examination in otology.

Harold I. Lecks, the urology prize by Professor Thomas to the senior passing the best examination in urology, and the C. V. Mosby Company prize to the senior with the highest average in medicine, a year's subscription to the *American Heart Journal*.

Jerry Zaslow, the dermatology and syphilology prize by Professor Wright to the senior presenting the best record in the course for the junior and senior years.

Mary Catherine Cortner, the hygiene and public health prize by Professor Hartley to the senior presenting the best sanitary and health survey of his home town.

David S. Ruhe, the senior surgery prize by Professor Babcock, a silver medal and \$25, to the junior presenting the best report of the junior surgical clinics for the year.

Milton M. Cahn, the junior obstetric prize by Professor Arnold.

John T. Ealy, the surgical procedures prize by Dr. J. N. Coombs to the junior presenting the best report on surgical procedures.

Charles B. Hess, the C. V. Mosby Company prize, one year's subscription to *Surgery*, for the highest average in surgery for the senior year.

University of Texas

Interest is being shown in the attempt to organize a medical school glee club at the University of Texas, Galveston, under the direction of Mr. Charles Spence, a sophomore.—William Mills has been elected president of the freshman class at the medical school, and R. V. Jones, president of the sophomore class.—An innovation in the curriculum for the senior students is a one week's externship in pediatrics at the Jeff Davis Hospital in Houston, which is required for credit in the course.—At the official opening of the school year, October 1, Dr. Raymond Gregory, newly appointed professor of pharmacology and medicine, was the principal speaker; his address dealt with the importance of laboratory courses in the medical curriculum, the value of wide reading on the part of the student and the rewards of scholarship.

Dr. Leake Lectures at Oklahoma

Phi Beta Pi at the University of Oklahoma is sponsoring an annual lecture known as the Leroy Long Sr. Lectureship. The first address was given, March 12, at the University of Oklahoma School of Medicine, Oklahoma City, by Chauncey D. Leake, Ph.D., professor of pharmacology at the University of California Medical School, San Francisco, on the "History of Anesthesia."

College of Medical Evangelists

Five alumni of the College of Medical Evangelists, Los Angeles, are sponsoring an organization including fifteen students each from the junior and the senior class to promote fellowship between the students and the alumni of the school. At the meetings held once every three weeks, a part of the time is given over to an informal talk by some prominent physician of southern California, the remainder being spent socially. It is hoped that other alumni will sponsor similar organizations.

A new laboratory building was completed last January to house the physiology, biochemistry, pharma-

cology and physical therapy departments. The old South Laboratory Building, which formerly housed these departments, has been taken over by the outpatient clinic. In the clinical division at the college, in order to correlate more closely the didactic work with the clinical clerkships, it is planned that instead of giving formal lectures the teachers will conduct round table discussions or conferences with small groups of students.

Columbia Awards One Hundred Scholarships

The 133d session of Columbia University College of Physicians and Surgeons, New York, opened, September 19, with 410 students enrolled, including 110 freshmen, who came from twenty-five different states and from forty-seven different colleges and universities. At the opening exercises, September 25, George W. Bachman, Ph.D., director of the School of Tropical Medicine, San Juan, Puerto Rico, gave an address on "Medical Research in Latin America."

The College of Physicians and Surgeons has awarded 100 scholarships totaling \$36,675 for the present academic year. Most of the scholarships awarded were amounts ranging from \$200 to \$500.

Student Officers at Tulane

Arthur J. Wallace Jr., '41, University of Tulane of Louisiana School of Medicine, New Orleans, has been elected president of the senior class for 1940-1941; John B. Tribble, vice president; Hugh Murphy Yearwood, secretary; Richard Baker Austin Jr., treasurer, and James Harvey Johnston Jr. and Samuel Gwin Robbins honor council members.

Musical Medical Society

Phi Mu Phi, an honorary musical medical society of the University of Illinois College of Medicine, Chicago, created in 1931, is said to be the only organization of its kind in a professional school in this country. It is composed of a concert orchestra, a men's glee club and a "swing band" and gives several public concerts and radio appearances during the year. Sponsored by members of the faculty, medical students are encouraged to try to associate themselves with the society. Phi Mu Phi, which was founded by undergraduate students, offers an excellent source of recreation and extracurricular activity.

Pennsylvania State Board Questions

The following questions were given by the Pennsylvania State Board of Medical Education and Licensure at the examination in Harrisburg, July 9, 1940:

PHYSIOLOGY, PATHOLOGY, BACTERIOLOGY AND PHYSIOLOGICAL CHEMISTRY

1. State what further laboratory tests would be indicated in each of three specific findings in a routine urinalysis.
2. Outline briefly the function of the liver.
3. What are the normal findings in a gastric analysis? Give the significance of each of the more common abnormal findings.
4. Outline the laboratory investigations called for in a case of edema.
5. What is the meaning and the significance of each of the following: (a) nystagmus? (b) reaction of degeneration? (c) aphonia?
6. Describe briefly the vasomotor system. How may it be seriously altered functionally? pathologically?
7. What is the physical consequence of a deficiency (a) in vitamin C? (b) in pituitary secretion in childhood?
8. Give specific directions for obtaining and for transmitting to the laboratory suitable specimens for determining the etiology (a) of purulent conjunctivitis; (b) of acute pharyngitis. What micro-organisms are suspected in each?
9. State the significant feature in bacteriologic investigation that identifies each of the following: (a) *tubercle bacillus*; (b) *Klebs-Loeffler bacillus*; (c) *Spirochaeta pallida*.
10. In a case of progressive debility without fever in a middle-aged man, what laboratory investigations might establish the cause?

PUBLIC HEALTH ASPECTS OF RHEUMATIC HEART DISEASE

INCIDENCE AND MEASURES FOR CONTROL

HOMER F. SWIFT, M.D.

NEW YORK

Public recognition of the nature and requirements of the problems of rheumatic fever and rheumatic heart disease has lagged far behind the attention given to other diseases of less numerical and economic importance. Some reasons for this attitude are as follows: Because limited facilities compel those in charge of public health services to consider how they may best expend funds, other pressing problems offer better opportunities for effective control. Death-dealing epidemic diseases earliest required reporting because quarantine measures often limited their spread. Again, discovery of a specific etiologic agent is a factor in making a disease notifiable, witness the discovery of the tubercle bacillus; but a review of the history of notification of tuberculosis reveals how slow has been the attainment of our approximately exact statistical knowledge concerning this disease, which today is probably not more than 75 per cent accurate, at least in respect to morbidity. Even less exact is the information derived from reporting syphilis. With the remarkable acquisition of knowledge concerning syphilis in the first fifteen years of this century, it was obvious that it could be stamped out and society spared the necessity of providing for invalids with late syphilitic vascular, nervous and mental disease annually costing many times the outlay for efficient prophylaxis. Nevertheless prudence overcame prudence, and only recently has there been undertaken in this country what was possible from the scientific point of view twenty years earlier.

Another crippling disease might well be contrasted with rheumatic fever in its public health aspects, namely poliomyelitis. Both diseases in their early acute phases kill only a small portion of those affected; both cripple, one obviously, the other insidiously. In poliomyelitis, a single attack confers almost complete immunity, in rheumatic fever one attack apparently increases susceptibility to recurrences which induce progressive cardiac crippling, eventually leading to death. Knowledge concerning the virus causing infantile paralysis has not led to any effective therapeutic or prophylactic measures. While the number of symptom-free cases of poliomyelitis may be many times that of the crippling cases, the latter comprise only a fraction of the individuals suffering from rheumatic heart disease. The relative numerical prevalence of these two diseases can

be inferred from the following figures:¹ In New York City, during the ten year period 1930-1939, there were reported 7,811 cases of poliomyelitis with 693 deaths, but this includes the epidemic of 1931, with 4,138 cases and 504 deaths, and that of 1935, with 2,054 cases and ninety-one deaths. While there are no data available for the number of cases of rheumatic fever, in 1938 alone there were reported 147 deaths from rheumatic fever and 958 from rheumatic heart disease.² As indicated later, these figures are probably too low; nevertheless the mortality in a single year from rheumatic fever and rheumatic heart disease was almost double that of poliomyelitis for a whole decade. In other words, the economic importance of rheumatic fever is apparently much greater than that of infantile paralysis. The relative attention given them by the lay public, health authorities and vital statisticians is in striking contrast. Some idea concerning the occurrence of poliomyelitis can be gained from our public health reports, relatively little concerning the other because it is not reportable. And searching among the reported deaths from heart disease gives only an inkling of the relative part played by rheumatic fever because this well recognized etiologic factor has but recently been required on death certificates. When the desirability of reporting is urged, one encounters the objection of mistaken diagnosis both during illness and in deaths without postmortem examinations; but, in general, vital statistics, even with their recognized inaccuracies, are our most useful source of knowledge concerning the relative frequency and economic importance of various diseases and of the trends of increasing or decreasing incidence. Argument directed toward the desirability of attaining this information by requiring notification should not be regarded as fanatical. Even if the machinery cannot be all set in motion immediately it would be worth starting, for the two other great disabling chronic infections, tuberculosis and syphilis, are on the decline; and the existing institutions caring for patients with tuberculosis and late syphilitic nervous and mental diseases may in part be eventually devoted to the more effective rest treatment of patients with rheumatic heart disease. Had rheumatic fever been made a reportable disease twenty years ago, we could today present fairly accurate figures concerning the relative urgency of the problem and hence might better provide the technic whereby one class of invalids could be substituted for another.

With the requested reporting of rheumatic fever as an etiologic factor in death from heart disease, in New York City, some idea of the relative death-dealing effects of other infectious diseases and rheumatic fever may be obtained. In 1938³ there were 3,833 deaths from all forms of tuberculosis contrasted with 1,105 reported for rheumatic fever and rheumatic heart dis-

ease. Or contrast the mortality from rheumatic fever with that from the following reportable diseases in the same year: diphtheria twenty-six, measles forty-two, whooping cough 105, scarlet fever seventeen, epidemic meningitis fifty-three and poliomyelitis four, a total of 247.⁴ In other words, there was a ratio of 4.5 deaths from rheumatic fever and rheumatic heart disease to each death from all of these six reportable infectious diseases combined. Hedley⁴ reported a mortality ratio of 3.6 to 1 for the same diseases in Philadelphia in the year 1936. These figures are presented not with the idea of doing less with the required reportable diseases but of emphasizing the relatively greater size of the rheumatic fever problem and the consequent desirability of also making this disease notifiable.

STATISTICS OF NEW YORK HEART ASSOCIATION

The lack of approximately reliable data from the Bureau of Vital Statistics of New York City until recently has fortunately not left us entirely without some other means of estimating the size of the problem, because the New York Heart Association for more than

enough active rheumatic carditis to require special clinic care. This, however, is only part of the story among sick rheumatic children, for there were a total of 7,759 children treated by these clinics, including new cases, readmissions and old cases. If we apply the modest figure of 66 per cent as the proportion of these patients who probably had rheumatic fever as an etiologic factor in their illness, we see that at least 5,000 children were in need of supervision because of rheumatic heart disease in these clinics alone.

While this case load for children is impressive, it is obviously much less than the total imposed by rheumatic fever, first because many cardiac children do not enter these clinics and second because the long periods of invalidism due to rheumatic heart disease usually come later in life. This is illustrated by the data for 2,430 adults admitted for the first time to these clinics in the year 1938. Among these the etiologic factor was definitely given as rheumatic fever in 715, or 29 per cent, and unknown in an additional 8.1 per cent. Combining the new admissions of both children and adults, it is seen that this disease made approximately 37 per cent of the case load in new cases in this four year period with an additional 11 per cent in the unknown category. It seems safe, therefore, to consider 45 per cent as a safe estimate of new patients applying to these clinics for care whose heart disease rested on a rheumatic basis. If we apply the estimate of 45 per cent to the total cases on the active roster of these clinics, it appears that at least 8,700 were of rheumatic origin. The exact number of these patients who were suffering from active rheumatic inflammation of the heart valves and muscle compared with disability due to scarring, and simple hypertrophy and dilatation is a matter of conjecture, but that it was several thousand can be safely stated for the following reasons: Only exceptionally do children with rheumatic heart disease have symptoms of cardiac failure without active rheumatic disease. One may therefore take it that such a child needs the type of treatment that will help him overcome a chronic infection, as well as therapeusis for relieving the signs of cardiac insufficiency. While the element of active infection may not be playing a role in inducing symptoms among so high a proportion of adults, because by this time scarring of the tissues and wearing out of a long overworked mechanically subnormal organ are important factors in cardiac failure, still the baleful influence of active rheumatic disease in adults is well known. For example, careful microscopic examination of the hearts of rheumatic subjects dying from chronic heart disease has revealed evidence of active rheumatic inflammation in the organs of from 70 to 80 per cent of those under 40 years of age.⁶ While figures are not at present available concerning the age grouping of the eight to nine thousand clinic patients with rheumatic heart disease, it is a well recognized fact that relatively few outpatient clinic patients fall into the old age groups. By applying this knowledge to our analysis of the problem of rheumatic infection among the more than 19,000 cases of heart disease seen in these fifty-six clinics in a single year, 1938, it is obvious that in many thousand of them active rheumatic infection was playing an important role in inducing invalidism.

TABLE 1.—New Cases of Rheumatic Heart Disease Admitted to Cardiac Clinics of the New York Heart Association, 1935-1938

Year	Clinics	New Cases			Etiology Rheumatic Fever		Etiology Unknown		Rheumatic Fever and Unknown	
		Children	Adults	Total	No.	Per Cent	No.	Per Cent	No.	Per Cent

twenty years has gathered statistics from the patients in the various cardiac clinics which met the minimal requirements of that association. There are now fifty-six such clinics, where the diagnosis follows a uniform plan laid down in the official criteria; hence the data are probably more accurate than any gathered by compulsory notification. The admission figures for four years are shown in table 1.⁵

In 1938, among 1,031 children admitted to twenty-five children's cardiac clinics, 59 per cent had a definite diagnosis of rheumatic heart disease and in another 18 per cent the diagnosis was unknown. All students of this disease recognize that a fair proportion of patients with rheumatic carditis have no other outstanding symptoms of rheumatic fever; hence a rate of 76 per cent of rheumatic heart disease among this 1,031 new cases seems a very conservative estimate. The actual number was 794. In the same year 126 other children who had been previously discharged were readmitted; probably most were suffering from recurrences of rheumatic heart disease severe enough to require medical attention. In children these relapses are indicative of reactivation of the rheumatic inflammation in the heart muscle and valves, so it seems safe to add 100 to the 794, or a total of at least 900 who were admitted to these twenty-five outpatient children's clinics with

Special attention has been given to these only approximately correct data because they represent the results of study by a well qualified group of physicians; they include only living patients and hence indicate somewhat the size of the facilities required for the adequate care of these patients, if we regard as good practice provision for prolonged and supervised rest, proper nutrition,

and guarding against such infection as apparently set off the rheumatic explosion. They by no means include all the patients in New York City who probably require professional care because of rheumatic heart disease nor do they represent the total case load imposed by rheumatic fever, which in the acute and subacute stages forces bed rest on many of its victims; although, let it be mentioned parenthetically, the practice of relieving with drugs a rheumatic patient of his painful and rest-imposing symptoms and then allowing him to become ambulatory has by no means become antiquated. The necessity for providing beds for other more acutely ill patients often causes hospital authorities to urge the removal of the symptom-free rheumatic fever patient to his home or to the outpatient department when good practice indicates prolonged bed rest. The average child with his first or second attack of rheumatic fever often has little and only transitory arthritis and is usually free from any symptoms of heart involvement even though there are physical and laboratory signs of active carditis. Were adequate and properly organized sanatoriums available for these patients, it is doubtful whether they should be kept long in general hospital wards, because it is difficult to maintain adequate disciplinary and recreational facilities and provide against reinfection with streptococci, which may induce a serious relapse. In other words, under existing organizations a patient who requires chronic treatment is placed under conditions in which acutely ill individuals receive special attention. Certainly, transfer to outpatient care is not the proper answer to his requirements, and yet in many instances this is the only way of meeting the demands imposed by a large number of patients of all classes.

OTHER SOURCES OF INFORMATION

Because size, both relative and absolute, is one of the important factors which accentuate the urgency of any public health program, it seems worth while to explore further the sources of available information. Because no etiologic data are recorded in the official lists of death from heart diseases, if one is to obtain any idea of the approximate number of deaths in which rheumatic fever has had an important role in the ultimate fate of the decedents one must use some such device as applying etiologic interpretation gained from studies of large groups of cardiac patients of all classes and ages.

While heart diseases in general have become the leading cause of death, and obviously most of these fatalities occur among older people, nevertheless in the age periods 5 to 30, when rheumatic fever provides the chief etiologic background for the heart failure, heart disease stands very prominent among the three most important causes of death in both New York City and State, as is illustrated in the figures abstracted in table 2.⁷ Such official figures indicate most clearly how important it is not to relegate the interest in heart diseases entirely to the field of geriatrics.

While it is generally recognized that rheumatic fever plays the chief etiologic role in cardiac deaths in the age groups 5 to 30, it is desirable to gain some impression as to its relative importance later in life. For this purpose one may interpret in more detail the official lists of death with knowledge gained from etiologic analysis of large groups of living cardiac patients. Among the most reliable data in this respect for an analysis of New York vital statistics are those of Wyckoff and Lingg⁸ because they include patients from hospital wards, outpatient clinics and private practice. If one applies such distribution coefficients to the cardiac deaths in New York State in 1938, included under the categories 90 to 95 of the 1929 International List of the Causes of Death, and further subdivided according to decades, one obtains the figures shown in table 3.⁹

Some interesting points emerge from such a tabulation. In recent years the emphasis laid on the prevalence of rheumatic heart disease among children and of degenerative cardiovascular disease in the aged has diverted our attention statistically away from the influence of rheumatic fever as a cause of cardiac disability in the fourth and fifth decades; and yet, if the figures shown are approximately correct, rheumatic heart disease takes a larger toll in the second half of life than in the first. Such an impression is strengthened by the reported deaths from rheumatic heart disease in New York City for the same year.² Among these 958 deaths 377, or 39 per cent, were in subjects under 30, 411 in

TABLE 3.—Total Number of Deaths, Categories 90-95, New York State in Age Groups 1-59

those between 30 and 59, and seventy in patients over 60 years of age; but this does not include those reported as dying from rheumatic fever. Hedley⁴ has made special reference to the importance of rheumatic heart disease as a cause of death in the latter half of life because he found in Philadelphia during 1936 that only 40 per cent of decedents from this affliction fell in the

9. Abstracted from tables 18 and 19, pp. 46-49, Fifty-Ninth Annual Report of the New York State Department of Health, 1938.

first three decades of life. DeGraff and Lingg's¹⁰ analysis of a large group of fatal cases with rheumatic fever as the background for the crippled heart showed definitely that the fourth decade contains many fatal cases; and among Wyckoff and Lingg's⁸ living patients in the sixth decade almost 30 per cent could attribute to rheumatic fever an etiologic role in their heart disease.

The difference between the number of deaths in New York City, estimated in table 3, 2,114, and the 958 reported as due to rheumatic heart disease, obviously requires some discussion. An additional 147 deaths were reported as due to rheumatic fever, which immediately raises it to a total of 1,105. Moreover, the figure 2,100 does not seem out of line with data derived from the case load imposed by rheumatic heart disease in the New York Heart Association cardiac clinics in 1938. As already mentioned, between 7,000 and 8,000 patients seen in that year were reasonably certain to have had rheumatic fever as a cause of their disability. DeGraff and Lingg¹⁰ found an average of three years between the onset of heart failure and the final episode; in other words, each death might be considered to represent an average of three years of invalidism of a degree that would cause the patient to seek medical assistance. Applying the factor 3 to the total of 2,100 estimated deaths would give an invalidism rate of 6,300, which is less than the number of patients with rheumatic heart disease seen in the New York Heart Association clinics alone; for to this number should be added those in other clinics, private patients and those who because of marked disease were no longer ambulatory. The total estimate in table 3, therefore, seems conservative, even though the age distribution may be inaccurate.

In order to determine the probable size of the rheumatic fever and rheumatic heart disease problem for the entire country, some other statistics must be considered. Hedley¹¹ has recently presented data indicating that the incidence of rheumatic fever is declining. This is based on the thesis that the number of deaths in the age groups 5 to 24, classified under categories 90 to 95 in the International List of Causes of Death of 1929, or of categories 87 to 90 of the 1920 list, might be considered a valid index of the incidence of rheumatic heart disease and that changes in the rates per hundred thousand based on this index could be used as a basis for indicating the trends as to the incidence of rheumatic heart disease. Much valuable information, presented in Hedley's paper, will be discussed later. That the total deaths from heart disease in the age period 5 to 24 has rheumatic fever as a background in most instances is obvious, but it is equally obvious from both clinical and pathologic experience that the total deaths in this age group by no means represent the total deaths brought about by rheumatic fever. Indeed, Hedley⁴ earlier emphasized the importance of rheumatic heart disease as a cause of death in the last four decades of life. In New York State during the year 1938 one finds from table 3 that among the estimated 5,500 deaths from rheumatic heart disease there occurred 1,494, or 28 per cent of the total, within the first three decades. If one includes only the cardiac deaths in the age group 5 to 24, the total was 1,129, or roughly 20 per cent of the total estimated as due to rheumatic carditis. If

this ratio holds for the entire United States, it would seem that the total deaths from rheumatic heart disease for the year 1936 would be five times the 6,321 reported by Hedley as occurring in the age group 5 to 24 inclusive, or 31,600. If we further apply to this total the factor of 15, the average number of years that DeGraff and Lingg¹⁰ found to elapse between the onset of rheumatic fever and fatal heart disease, we could estimate that there were about 460,000 persons in the United States whose hearts had been damaged as a result of rheumatic fever. Paul,¹² from a study of the incidence of valvular heart disease among school children, drafted men, hospital patients and insured persons, estimated that the total number of cases of rheumatic heart disease in a population of 100 million would be about 840,000; this rate applied to the present population of the United States would give about 1,100,000 cases. As this is more than double the number I have estimated from mortality rates, it seems that my estimate is probably not too large. Another check on my estimates might be derived from the annual death rate from valvular heart disease among policyholders of the Metropolitan Life Insurance Company reported by Dublin and Lotka;¹³ for the year 1930 that rate was 45 per hundred thousand. This, applied to a population of 130,000,000, would give a total of 58,500 deaths a year from valvular heart disease, a figure nearly double that derived from my estimates. This multiplied by 15 would indicate almost 900,000 cases of valvular disease and if, as seems probable, higher rheumatic fever rates existed in the 1920s, the total would easily be raised to a million, for let it be emphasized that the rheumatic fever of ten to twenty years ago is having an influence on the rate of cardiac deaths today.

CLIMATIC INFLUENCES ON INCIDENCE OF RHEUMATIC HEART DISEASE

Among the factors that have received much attention in the etiology of rheumatic fever are the geographic conditions under which the disease appears to wax or wane. These are naturally important in considering public health aspects of rheumatic heart disease, for the chronic and relapsing nature of the infection furnishes an ideal setup for testing the influence of various environments, could it be confidently stated that some offered probability of arresting its progress.

A striking feature of the rheumatic infection in this latitude is the seasonal variation, with the highest incidence in late winter and spring; but when summer comes fewer new cases occur, and those with acute symptoms improve. This indicates that a tropical environment might explain the phenomenon, were similar seasonal influences not seen in a more northern area such as London, where a really hot day is rare. There, however, the low point on the incidence curve corresponds with the combination of greatest amount of sunshine, highest mean temperature and lowest moisture.¹⁴

The many surveys indicating the rarity of the disease in the tropics and subtropics and the lower incidence reported in our own Southern states have suggested the importance of climate to such an extent that some people think that all they require to be cured is to move to Florida or California. In view of these opinions it becomes necessary to investigate the available data more closely. The most encouraging reports were those

of Coburn,¹⁵ who moved a few children with chronically active rheumatic fever to Puerto Rico and noted complete subsidence of symptoms, with recurrence of active carditis when the patients had resumed their residence in New York. Jones and his co-workers¹⁶ noted similar improvement in a group of children sent from Boston to Miami for one season, but the results were subsequently less encouraging. One might remark, parenthetically, that the climate of Miami is far from tropical and that numerous fresh respiratory infections are transported from the North to that city daily during the winter. The factor of respiratory infection is therefore not eliminated by a possibly favorable geographic site.

Several communications have appeared in recent years indicating that rheumatic fever may not be so rare in the tropics as might be implied from the reports of Tertius Clarke¹⁷ and others. The coastal borders of southern India and Ceylon are about as tropical as any regions inhabited by man, but Fernando¹⁸ and Stott¹⁹ have found a fairly high incidence of rheumatic heart disease among the natives, with the same relative differences in incidence among the poor and well-to-do as is seen in New York and London. Indeed, crowding, poor housing and poor nutrition seem to play almost as important unfavorable roles in hot as in cold climates. The type of clinical manifestations of rheumatic fever under different climatic environments must be considered in judging the reports from different localities. In this country many clinicians have noted the relative infrequency and mildness of polyarthritis in the South, compared with the Northeastern Seaboard. Stott¹⁹ emphasizes the necessity of estimating the incidence of rheumatic fever in India from the occurrence of mitral valvular disease rather than from that of migratory polyarthritis. On the other hand, the influence of climate seems to be strikingly brought out by such investigations as that of Paul and Dixon²⁰ among three large groups of American Indian children living in different latitudes. Even though of analogous anthropologic stock, with housing conditions not dissimilar, those living in southern Arizona had only about one tenth as much mitral valvular disease as those in Idaho and Montana.

Any large survey, then, that will throw light on the influence of climate is welcome. Hedley's¹¹ recent report presents an analysis of the cardiac deaths among decedents between the ages of 5 and 24 over the period 1922 to 1936 and covers the entire United States. The value of these data rests on the approximately correct assumption that most of the cardiac deaths in this age group have rheumatic fever as a basis. A perusal of these data shows the difficulty of judging correctly the influence of such a simple factor as climate, for we immediately meet the complicating factors of urbanization, race and economic status of the inhabitants; and in the state of Florida, for example, one must consider the probability that during the past two decades many cardiac invalids have migrated from less salubrious climates.

The first serious factor in the analysis of the crude figures is the relatively greater death rates among Negroes compared with white persons. For example, among the twenty cities having the highest rate in the three years 1930-1932 the Southern states include three, namely Jacksonville, Memphis and El Paso; but, when the data for these three are separated into white and colored groups, the rates for white persons fall far below that for the colored. Again, if we pick the cities of 100,000 or more with a rate of 10 or less per hundred thousand among the white population, we find that here the rate among Negroes is from two to four times as high. One may legitimately ask whether these differences are due entirely to racial factors or in part to such economic elements as poor food, housing and clothing. An interesting commentary on the relative influence of climate and economic status is furnished by the rates in Boston, 31.3, Somerville, 16, and Cambridge, 11.8 per hundred thousand, respectively,

in the years 1930-1932. The climatic environment in these three contiguous Massachusetts cities is essentially the same but the economic conditions differ. The differences in the rates of deaths probably due to rheumatic heart disease in the white and colored races, respectively, is further emphasized by an analysis of Hedley's data for the Southern states during the period 1922-1929, where the rates among Negroes were two to three times that for white persons.

Even considering the combined rates for white and colored, a favorable effect of the southern climate can be inferred from these tables, for when one compares the rate among white persons in the various states of the South with that for the entire population in the northernmost states, the balance is in favor of the Southern states in practically every instance. Again, comparison of the rates in the northern tier of states with those of the southernmost yield additional interesting information (table 6). The rate for Maine is lowest of any in its tier and as low as that among the white population of Virginia, Kentucky or Florida. The rate for Vermont is almost as low; while New Hampshire, situated between these two, has a distinctly

higher rate, possibly because of a larger industrialized population. The three northern tier states with the largest urban population, New York, Ohio and Michigan, had by far the highest rate; then in the rest of the northern tier with the exception of Montana the rate is practically the same as that of New Hampshire. Montana must be classed among the mountain states where

Mountain states should probably be avoided by sufferers from this disease, if they are searching for the most beneficial climate.

SANATORIUM THERAPY OF RHEUMATIC
HEART DISEASE

While the nature of rheumatic fever and rheumatic heart disease and the size of the problem have long appeared to make it amenable to public health consideration, as far as can be learned, only in London have extensive provisions been made for the care of the majority of rheumatic children. In many of our cities the school authorities have provided facilities for education, transportation and school room environment specially arranged for children with heart disease. Special cardiac outpatient departments, often supervised by local heart association specialists, attempt to furnish medical care for these children; and in a few cities there are good convalescent homes largely supported by private philanthropy, with private physicians in attendance. All of these efforts, however, have apparently only scratched the surface. It is fortunate, therefore, that we have had one large scale example of how the problem might be attacked; and there are also some data indicating favorable results from this experiment, which is being conducted in London.

The London County Council's Rheumatism Scheme has been slowly developed since 1926.²⁴ Fundamentally it is based on two theses: first, that rheumatic fever is a chronic infection and hence its victims should receive adequate chronic treatment; and, second, that the relapsing nature of rheumatic fever and the consequent heart disease demand supervision over many years. It is a cooperative effort on the part of the school and health authorities, which have enlisted under their supervision the public and private institutions already organized for the care of rheumatic children; and in addition there have been built, outside of London, special units containing a total of 900 beds for hospitalizing all cases of rheumatic fever, chorea or active rheumatic heart disease in school children under

16 years of age for at least six months. This has required a minimum of one bed to 550 school children.²⁵ The working of the scheme is best illustrated in the chart of the organization. The center is the rheumatism section in charge of a full-time medical officer with an adequate staff; through this section all applications for admission to the special hospital units pass. There are two types of units, one for active cases and the other for convalescent children who have recovered from

Hedley found the highest rate. Indeed, Utah leads all the states with a rate of nearly 35 per hundred thousand; and the Mountain states as a group with a rate of 22.6 were exceeded only by the group of Middle Atlantic states New York, New Jersey and Pennsylvania, where the rate was 27.6. As Arizona and New Mexico had distinctly the lowest rate of any mountain state, a southern latitude again appears to exert a favorable influence.

With minor variations, a trend in incidence of fatal heart disease in the age groups 5-25 has been steadily downward over the past two decades; and this tendency is in line with that noted by Atwater,²² by Cohn²³ and by Dublin and Lotka.¹³ It is interesting to see that the percentage fall has been less in those Southern states where the rate is low, such as Alabama and Mississippi; but there the high rate among Negroes did not drop in the last decade; and in the South Atlantic states, where there was an appreciable fall of the rate among the white people during this period, that among the colored was stationary or rising. It must be mentioned, however, that the fall in the death rate from heart disease in the age group 5-25 does not prove definitely that there has been a corresponding fall in the incidence of either rheumatic fever or rheumatic heart disease, because, as already mentioned, this age period comprises only a fraction of all the cardiac deaths resulting from rheumatic fever; and possibly better treatment has lengthened the life expectancy of patients with rheumatic heart disease so that the fatal outcome may not be manifest until later age periods. Such, indeed, has been the result of modern therapy in diabetes; but even if Hedley's analyses indicate no more than that, such an encouraging gain is well worth recording.

In summary, then, Hedley's data indicate that at least two environmental conditions are operative and should be considered, namely climatic and economic. The Southern states appear to furnish the most favorable environment for patients with rheumatic heart disease or at least the least favorable environment for its development, while the Middle and Northern

recent attacks. On discharge from these hospital units the patients again pass through the rheumatism section, which assigns the child to the educational category its physical state requires and also to the proper medical supervisory authorities. In this rheumatism section there is a register of each child reported as suffering or having suffered from rheumatism and this is used to supervise and record his treatment until he is 16; and for those patients who have received institutional care under the scheme there are more complete records which are available for reference until the patient attains the age of 18. Physicians in supervisory centers situated either in the schools, in private hospitals or in outpatient clinics supported by the scheme examine these patients often enough to detect recrudescence of rheumatic fever even though of slight degree; and in such instances the patient is referred again to the proper institution for treatment. These institutions are essentially hospitals or sanatoriums with both medical and educational staffs, for it is realized that suitable education and special training of these patients are important elements in their treatment. The individual hospital units have all physical provisions necessary for good medical care, including outdoor treatment in bed when that is advisable. The home conditions of all active cases are investigated, and where obviously inadequate or unfavorable, a report is submitted to proper authorities with the object of having these families better housed.

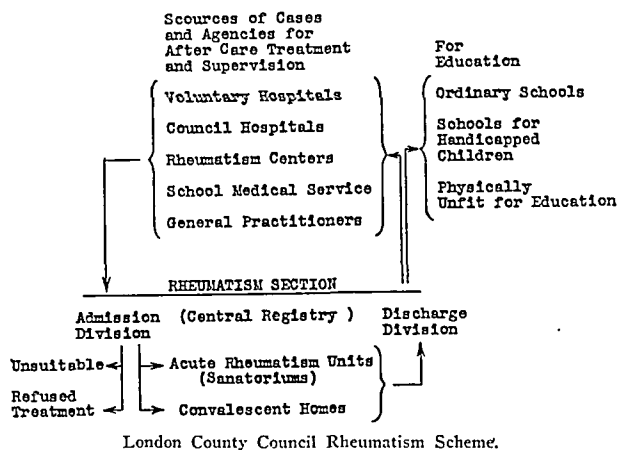

Physicians who have followed rheumatic children for the past fifteen or twenty years feel that the expense of the scheme has been justified by the statistical results. In 1926, for example, 2 per cent of the school children of London were suffering from acquired heart disease, while in 1936 the incidence had fallen to 0.8 per cent. Furthermore, the number of children of school age whose chronic cardiac crippling was of such severity as to require care in special educational units during a four year period has dropped steadily as follows: 1934, 320; 1935, 232; 1936, 153; 1937, 114.²⁶

In urging the importance of providing similar facilities for the chronic care of patients with rheumatic heart disease, one often meets the objection that we cannot judge accurately the benefits of sanatorium therapy because we have no large series of untreated patients for comparison. One might reply that practically all studies and statistics concerning the life history of rheumatic heart disease deal largely with patients who fall naturally into such a control group because they have had relatively little institutional treatment. On the other hand, even admitting the desirability of a simultaneously observed noninstitutionalized control group made up of rheumatic children of similar age and severity of carditis, it appears probable that such a striking diminution in the incidence of both rheumatic valvular disease and of crippling carditis as has been observed in London might properly be attributed to the measures so extensively provided for prolonged treatment of children with active or recent rheumatic fever.

PROBABLE SANATORIUM REQUIREMENTS FOR RHEUMATIC CHILDREN IN NEW YORK CITY

As already noted, London is the only large city which has attempted to provide care for rheumatic children on an extensive scale; and as the scheme there elaborated has been slowly developed, it probably

rests on a sound basis. Doubtless the present war has disrupted its working seriously, but it has been operative long enough to serve as a model. It therefore might be profitable to compare the facilities in New York for meeting a similar problem. If provision for hospitalization should be made at the same rate as that existing for the London school population under 16 years of age, i. e. one bed for 550 children, 1,760 beds would be needed. In 1934, 2,181 children under 14 years of age with heart disease were discharged from the hospitals of New York City; among them 1,441, or 66 per cent, were kept in the wards less than one month and another 414, or 19 per cent, were in the wards between thirty-one and sixty days.²⁷ As the majority of these 1,855 children were doubtless suffering from active rheumatic carditis, it is obvious that the case load here requiring the type of treatment furnished in London was as large as existed in that

city. Moreover, the large group of children with simple rheumatic fever or chorea were not included, nor were those seen only in outpatient clinics enumerated. For the special care of more than 2,000 children there were 187 beds, but in only one of the institutions, Irvington House, were physicians in residence and adequate facilities available for the complete study of infectious and cardiac activity. Subsequently the St. Francis Sanatorium for Cardiac Children has been established at Roslyn, Long Island, with recent plans for enlarging its capacity to 125 beds. Therefore about 300 beds are now available to meet a situation probably demanding from three to five times as many for children alone. The New York Heart Association cardiac clinics are probably as well organized as the London supervisory centers, and in many of them the technic for following the natural history of rheumatic heart disease is much better. New York City has special school classes for physically handicapped cardiac children and provisions for their transportation. What we lack is a central rheumatism section comparable to that in London and the provision for adequate sanatorium care. A central registry for these patients is obviously desirable, for only by analysis of records of rheumatic patients such as would be compiled by such a system will it eventually be possible to determine the relative efficacy of different treatments. The New York Heart Association has not been unmindful of the importance of compiling such records, and its Research Committee has many thousand under accumulation and analysis. But the effective study of such data should not rest on the efforts and

26. London County Council Annual Report 3:44 (part 2, Public Health), 1937.

27. Facilities in New York City for the Care of Patients with Heart Diseases, New York Heart Association, 1936, p. 16, table 5.

enthusiasm of a small group, for in the case of a chronic disease such as that presented in the rheumatic heart the problem is longer than that of the life of any single individual or group; hence an adequately financed, permanent, supervisory and statistical organization should be provided which will have as its object the long-range study of the adequacy of prophylaxis and therapeutics. A registry of patients with tuberculosis by health authorities has been feasible and useful. Numerically the problem of the rheumatic child and adolescent is as great as that of the tuberculous youth of this city. The permanent arrest of the active infection in the heart of the rheumatic child would seem to offer as great a chance for a useful economic life as the arrest of tuberculous infection of the lung. What appear to be needed are adequate facilities for establishing that arrest at the earliest possible moment.

PROPER CARE IN DIFFERENT PHASES OF DISEASE

The problem of the proper care of rheumatic children differs in different phases of the disease. Obviously most of them with the symptoms of acute arthritis, carditis or chorea will be sent to general or pediatric hospitals if they are not cared for in their own homes. While they are acutely ill the indications are relatively simple, and the ordinary general hospital is willing to assume the burden; but as they pass into the subacute or chronic stage the problem becomes more difficult with at present scant facilities for its solution. It is my firm conviction that at this stage the average child would be best treated in an institution where the special indications imposed by his disease can be adequately met. The retaining of a rheumatic child in general wards subjects him to greater danger of reinfection with hemolytic streptococci than would exist in a ward where the serious implications of such reinfection are recognized and measures are instituted for their prevention. The educational, recreational and psychologic requirements of these chronically bedridden and convalescent patients can best be met in special groups than among patients who are more acutely ill and undergoing more rapid recovery; their careful and gradual restoration to normal activity will be more effectively supervised and their response to exercise more easily noted than where these activities have less influence on the ultimate outcome. Convalescence from rheumatic carditis should be chronic; and to make a child in this condition compare the slowness of his recovery with that of a convalescent from pneumonia or appendicitis is to submit his psyche to a strain that may have permanent implications.

The low grade and chronic nature of many relapses, and often of first attacks, emphasizes the necessity of providing adequate care from the time of their detection, for it is practically impossible to have a patient with this type of low grade chronic disease admitted to the wards of general hospitals. Most children treated in outpatient clinics because of broken cardiac compensation are suffering from active rheumatic carditis. At present the only care possible for the majority of them is such rest as can be provided in their own homes under the unhygienic conditions that have favored the rheumatic relapse. Suffering from inflamed hearts and blood vessels, they are transported to the clinics in public conveyances, and both here and in the waiting rooms of the clinics they are often subjected to reinfection with types of streptococci against which they have not developed immunity. Is it any wonder that in so many cases the cardiac crippling is progressive? This

type of patient should be treated in the same manner as the one who has been transferred from general hospital wards after the acute illness, for their therapeutic requirements are similar.

An ideal sanatorium would provide for both the patient with active rheumatic carditis and the one in the convalescent stages, much as the tuberculosis sanatoriums contain both an infirmary and cottages or wards for prolonged convalescence. The average convalescent home for cardiac patients has evolved from the general convalescent home in charge of nurses, and with a minimum of resident medical supervision. A patient after recovering from the subacute inflammation in his heart would be better under the watchful eyes of physicians who understand the nature of his malady, even though his immediate care in this stage is largely in the hands of nurses, educators and child guidance specialists who should certainly be acquainted with his physical as well as his intellectual needs, just as the physicians and nurses should understand his particular psychologic problems.

The need for supervision of the patient on discharge from these special institutions brings up a number of questions in which the factors of familial and domiciliary environment and heredity in the etiology of rheumatic fever are at present inexplicably interwoven. Recent careful statistical analysis of rheumatic families made by Wilson and Schweitzer²⁸ and by Read and her co-workers²⁹ suggests that there is a hereditary factor at play in many instances. On the other hand, careful studies of rheumatic children's families by Paul and Salinger³⁰ suggest either that rheumatic fever may be a special manifestation of widespread respiratory infections or that these infections, suffered by most members of a family, set off the rheumatic explosion in a specially susceptible subject. Moreover, Paul's³¹ observations indicate that rheumatic manifestations are much more frequent in children than in adults subjected to the same respiratory infections which have spread through families. The status of a rheumatic patient in a family may be contrasted with that of a person with active tuberculosis: In the latter instance, the patient is a source of danger because he is a disseminator of tubercle bacilli; on the other hand, while the rheumatic patient may play a comparable role in respect to an etiologic agent of rheumatic fever, a greater danger seems to exist in the possibility that certain nonspecific respiratory infections spreading through the family will light up a new bout of rheumatic fever. In one illness the patient threatens his companions, in the other his companions threaten him.

Such peculiar susceptibility explains in part the frequency with which rheumatic relapses are observed in children who move from the favorable environments of a convalescent home to their own home. Indeed, from several aspects this move should be carefully prepared for and supervised. It should probably be postponed until after the active rheumatic fever season

has passed and should not occur when respiratory infections are rife in the family. Indeed, the home conditions may be so unfavorable as to indicate prolonged residence in a suitable foster home. The benefit of long foster home care compared with that in special institutions is now being studied by a special committee of the New York Heart Association.³² Moreover, the psychological adjustments imposed by the disease and by transfer from an institution or foster home to his own family environment would also be better supervised by properly trained persons than to leave them simply to chance. These considerations indicate that an efficient public health program would provide for investigating the families of most rheumatic children. If the housing conditions were obviously at fault, attempts would be made to have better physical environment provided in the newer and more hygienic houses now being built. If some other member of the family was acting as an obvious nidus of repeated respiratory infections, it would be important to treat him or else remove the rheumatic subject to less precarious surroundings. All the members of the family should be instructed concerning the dangers to the patient of respiratory infections and the means for inhibiting their spread.

Infectious elements may eventually be controlled by employing chemotherapeutic measures such as those tested by Coburn and Moore.³³ Obviously the administration of sulfanilamide or its derivatives to large groups of patients must be carefully supervised in order to reduce to the lowest degree the incidence of unpleasant or dangerous side actions. Parenthetically, it should be again emphasized that this drug has no curative influence on rheumatic fever but, on the contrary, often increases the severity of the rheumatic manifestations;³⁴ hence no drugs or other therapeutic measures now in our possession relieve us of the necessity of providing suitable institutional facilities for the care of rheumatic children.

Naturally, the suggested plan for the care of youthful rheumatic patients does not cover all the requirements imposed by rheumatic fever, but it does seem as though effective treatment during this age period might lessen the dangers of serious heart disease later in life and prolong the useful days of those who have been affected as children. Progressive cardiac crippling in the third and fourth decades is often the result of repeated or continuous rheumatic insults to the heart and blood vessels; hence in later life it is probable that prolonged rest and other measures directed toward increasing the patient's resistance to infection are indicated. To expect the average general hospital to assume this burden seems unreasonable; moreover, in suitably arranged sanatoriums these patients could be more effectively treated for approximately half the cost daily. The apparently favorable influence of Southern latitudes suggests the desirability of studying the treatment of some of the more intractable cases in institutions situated properly in the South.

We are too prone to demand satisfactory answers concerning etiology, immunotherapy and prophylaxis of rheumatic fever before attempting to provide facilities which seem to have a rational basis. It is well to recall

that Dr. Trudeau's therapeutic experiments were started before the discovery of the tubercle bacillus and that our present day treatment of the tuberculous patient is based on proper rest, diet and regulated exercise rather than on specific immunotherapy derived from our knowledge of the tubercle bacillus. The fact that many patients have recovered from tuberculosis without undergoing a rest cure does not relieve us of the responsibility of advising and providing for such cures; neither does the fatal outcome in many well treated cases relieve us of that responsibility. The necessity for continued investigation is still urgent in both diseases.

While many problems concerning rheumatic fever, rheumatic carditis and vasculitis remain unanswered, enough is known to warrant the institution of the measures suggested. The American Heart Association with its constituent membership of hundreds of cardiac clinics provides machinery for carrying out a part of the program. The United States Public Health Service is becoming interested to the extent of fostering both laboratory and statistical investigations. Chicago has made rheumatic fever a reportable disease. The New York Heart Association has evolved a most complete system of classification of heart diseases and established criteria on which efficient diagnostic data may be based; and this has been adopted by the American Heart Association.³⁵ The United States Bureau of the Census has agreed to separate rheumatic conditions as they appear to affect cardiac fatalities during the years 1937, 1938 and 1939.³⁶ What is really needed in vital statistics is an etiologic diagnosis in all fatal cases of heart disease in addition to the anatomic diagnosis now in vogue, and with a separate category for the unknown. In general, this rubric unknown can be applied to the entire categories 90 to 95 of the International List of Causes of Death, and only by applying probability figures to the various age groups can we obtain indexes which are probably valid if not strictly accurate. But why wait until death until we try to classify? The size of the problem and the necessity for providing proper care for the large group of patients with rheumatic heart disease would be more quickly learned by making rheumatic fever and rheumatic heart disease reportable. By and large the long-range effectiveness of our therapeutic and prophylactic measures will be measurable only if we have these data.³⁷

The seriousness of rheumatic fever to the individual and to large groups of individuals needs no arguing, but there has been less emphasis on the number of patients who have recovered from an acute attack without heart involvement and on the possibility of leading a long, useful and happy life even with a certain degree of distortion of the heart valves, if the patient has permanently subdued the rheumatic infection. It would therefore seem only the part of wisdom for society to provide the machinery whereby more patients may be moved to this more fortunate class, even though rheumatic fever still exists. This would be the objective of an efficient health program.

36. Dunn, H. L., and Hedley, O. F.: Statistics on Deaths from Rheumatic Heart Disease, J. A. M. A. 110:1413 (April 30) 1938.

37. The aid extended by the Children's Bureau of the Department of Labor to various states for the care of rheumatic children should provide facilities for studying some of the problems here discussed. Because of the chronic nature of rheumatic heart disease, the final results of therapeutic measures established now will be measurable only after fifteen to twenty-five years. Vital statisticians should therefore be quickly furnished with reliable figures with which to begin constructing valid numerical criteria applicable to a long term analysis.

SUMMARY

The size of the problem of rheumatic heart disease, from the standpoint of public health, indicates the desirability of widely extending the facilities for meeting the situation. The long period usually consumed in the evolution of rheumatic heart disease offers opportunity for interfering with that evolution at various times. Those unfavorable factors classified as economic are subject to improvement. Favorable climatic factors may be utilized. Because functional trauma of cardiac tissues harboring rheumatic inflammation probably increases the damage to these tissues, prolonged rest for such actively diseased structures is requisite and should be provided on a scale commensurate with the size of the problem. The role of hemolytic streptococcus infections in initiating the disease rheumatic fever and in inciting relapses indicates the importance of protecting these patients from such infections.³⁸ When these elements in a public health program are clearly recognized, there can be little doubt of its establishment.

CONTROL OF DIABETES MELLITUS

RELATION TO THE HEALING OF CLEAN AND
INFECTED WOUNDS AND TO INCIDENCE
OF INFECTION IN CLEAN WOUNDS

JAMES A. GREENE, M.D.
L. W. SWANSON, M.D.
AND
CARL A. JACOBS, M.D.
IOWA CITY

There continues to be a great deal of anxiety concerning the healing of wounds in cases of diabetes mellitus. Before the discovery of insulin a rising blood sugar level with increasing glycosuria was an ominous sign after a surgical operation or if the patient had an infected wound. The wounds of those who did not succumb to acidosis were likely to heal very slowly or become infected, and existing infection tended to spread. Since the advent of insulin, acidosis has been preventable and has ceased to be formidable. The other complications, however, continue to be menacing.

The idea is prevalent that such complications occur more frequently among patients with a high blood sugar level and glycosuria than among those who have a normal blood sugar level and no glycosuria. Study of the literature reveals that the methods advocated for the control of diabetes after surgical operations, or when the patient has an infected wound, vary considerably. Of the two methods which are most widely used, one¹ aims to maintain the sugar content of the blood

at a normal level and prevent glycosuria; the other² is to examine the urine every three to six hours and adjust the dose of insulin according to the degree of glycosuria. Those who advocate this procedure do not specify at what level the blood sugar should be main-

tained or the amount of glycosuria which is permissible, but they intimate that the urine should be kept approximately sugar free. A few authors do not favor such strict control. Some of them³ state that a slight elevation of the blood sugar level (to 180 mg. per hundred cubic centimeters) with a moderate degree of glycosuria is not harmful during the first few postoperative days, provided both decrease rapidly, whereas others⁴ advise that ketosis be avoided but ignore the blood sugar level and degree of glycosuria.

No one, as far as we know, has shown that the healing of clean or infected wounds is delayed or that infection develops in clean wounds more frequently in diabetic patients with hyperglycemia and glycosuria than in those with normal blood sugar levels and no glycosuria. It is for this reason that the present study was undertaken.

The records of 324 diabetic patients who had clean or infected wounds and were receiving a small or moderate amount of carbohydrate were analyzed in order to ascertain the frequency of delayed healing of wounds in relation to the height of the blood sugar and degree of glycosuria. The incidence was compared to that in a series of 158 nondiabetic patients of the same age and sex who had comparable lesions. In addition, in a series of thirty-five diabetic patients who had either clean or infected wounds the blood sugar level was kept between

operative wounds in cases of diabetes mellitus was ascertained. In the endeavor to decide whether the healing time has been normal or prolonged, each patient's record was studied by all three authors independently. The patients were divided into two groups, according to the blood sugar level and degree of glycosuria. Those whose blood sugar values were consistently below 200 mg. per hundred cubic centimeters with slight or no glycosuria were placed in one group, and those whose blood sugar levels were consistently above 200 mg. per hundred cubic centimeters with moderate to extreme glycosuria were placed in the other. In both groups the patients were classified according to the adequacy or inadequacy of the blood supply to the wound-bearing area. The blood supply to such areas in the head, neck, trunk and upper extremities was regarded as good in all cases. Arbitrarily, unless there was some statement in the record to the contrary the supply of blood to the

The foregoing observations raise the following question: How much more frequently is the healing of wounds delayed in patients with diabetes mellitus than in nondiabetic patients of the same age and sex with comparable lesions? This question is answered in table

lower extremities was regarded as adequate in all patients less than 40 years of age and as inadequate in all who were more than 40 years old. The patients were divided still further, depending on whether their wounds were clean or infected.

RESULTS AND COMMENTS

Table 1 shows that delayed healing of wounds did not occur as frequently in the patients with the higher blood sugar levels and greater degree of glycosuria as it did in those with lower blood sugar values. These observations do not support the prevalent idea that hyperglycemia and glycosuria hinder the healing of wounds in cases of diabetes mellitus. The data become even more impressive when it is pointed out that a vigorous but unsuccessful attempt was made to reduce the hyperglycemia in the more severe cases of diabetes. Furthermore the fact that maintenance of the blood sugar level above 250 mg. per hundred cubic centimeters had no deleterious effect on the healing time of wounds (table 2) substantiates the contention that hyperglycemia and glycosuria are not to be regarded as important factors.

3, which shows that the diabetic patient's chance of having delayed healing is approximately 4 per cent greater.

If this is true there are several possible factors which must be considered. First there is the question of the utilization of dextrose. In cases in which the dextrose intake is kept constant and the hyperglycemia and glycosuria tend to increase, the diabetes is growing worse and the patient's ability to utilize dextrose is decreasing. Under such circumstances, delay in the healing of wounds may be erroneously attributed to the hyperglycemia and glycosuria when, as a matter of fact, the patient's inability to utilize a sufficient amount of dextrose is a more likely factor. Except for the first few days after their surgical operations, our nondiabetic patients utilized from 300 to 350 Gm. of dextrose daily. On the other hand, our diabetic patients, except the thirty-five who were receiving very large amounts of dextrose, utilized only 100 to 170 Gm. Can the

greater incidence of delayed healing of wounds in diabetes mellitus be explained by this lower utilization of dextrose? We cannot answer this question at present. All our patients used enough dextrose to escape ketosis, but it is possible that the avoidance of ketosis alone is not sufficient to prevent delay in the healing of wounds.

It is generally agreed that patients with diabetes mellitus tend to develop arteriosclerosis earlier and to

a greater degree than nondiabetic persons. If this is true it could account for the greater frequency of delayed healing in cases of diabetes. Table 4 shows that the incidence of delayed healing of wounds in areas which were well supplied with blood was no greater among the diabetic than among the nondiabetic but when the wound-bearing area was poorly supplied with blood the incidence was higher among the diabetic. It is possible, therefore, that arteriosclerosis may be a factor.

Another possibility which must be considered is wound infection, but table 5 shows that diabetes did not interfere with the healing of infected wounds. In cases of diabetes it is the associated arteriosclerosis which accounts for the higher incidence of delayed healing of uninfected wounds. The relation of various factors to

rosis, however, increases the incidence of infection regardless of the blood sugar level and degree of glycosuria (table 8).

We do not wish to insinuate that the blood sugar level and degree of glycosuria should be neglected, for, if they were, it is obvious that we would have no accurate conception of the severity of the disease and would be unable to control it intelligently.

SUMMARY

In 324 cases of diabetes mellitus, the relation of the incidence of delayed healing of clean and infected wounds to the height of the blood sugar level and degree of glycosuria was studied.

In thirty-five cases of diabetes mellitus, the effect on the healing time of wounds of maintaining an unusually high blood sugar level and extreme degree of glycosuria was ascertained.

The incidence of delayed healing of wounds of 324 diabetic patients was compared with that in 158 nondiabetic persons of the same age and sex who had comparable lesions.

The relation of the blood sugar level and degree of glycosuria to the frequency with which infection developed in 323 originally clean operative wounds in cases of diabetes mellitus was ascertained.

As a result of our observations, we conclude that there is no relationship between the height of the blood sugar level and degree of glycosuria and the incidence of delayed healing of wounds or of infection in originally clean wounds in cases of diabetes mellitus. Delayed healing of wounds occurs approximately 4 per cent more frequently among the diabetic than among the nondiabetic of the same age and sex. The lower utilization of dextrose and the greater degree of arteriosclerosis are possible causes for this greater incidence.

ABSTRACT OF DISCUSSION

DR. ELLIOTT P. JOSLIN, Boston: All my life I have tried to treat diabetes just as aggressively as I could, and as I watched the cases over a series of years it has seemed as if the patients did better and better. Therefore it astonishes me somewhat to hear that one can get better results with the healing of wounds with high blood sugars than with low, with the abnormal than with the normal. I confess that I cannot furnish data to combat the authors' thesis, but before accepting it and changing a life's principle to treat diabetes just as aggressively as possible I would wish in the published article that the authors would give us more data relating to their observations. First, I am curious to know whether the blood sugars were fasting or taken after a meal. I would be interested to know whether the blood sugars were blood sugars on diets which were low or high in carbohydrate and calories. I would also like to know about the dosage of insulin and whether the patients were under treatment with it throughout the studies. Then too I cannot accept the classification of adequacy of the circulation of the extremities by a 40 year age limit. How many of the patients recovered? And in which group was the percentage of recoveries the highest? I cannot give information directly combating the paper but I would refer to an article of Dr. L. S. McKittrick (*Arch. Surg.* 40:352 [Feb.] 1940), of about a thousand operations in our series of patients, in which he showed that the results of the treatment of our surgical patients has been steadily improving, and I know that this has gone hand in hand with a more and more rigorous treatment of the diabetes. Whenever we hear statements which are a little different from those with which we have grown up, we should be very open minded. I am open minded and shall watch in the future still more to see whether patients do better in those clinics where higher blood sugars than are normal are countenanced than in those where medical supervision is more orthodox. It is difficult for me to believe

the incidence of delayed healing of wounds in patients with and without diabetes mellitus is shown in table 6. It is to be noted that diabetes had no deleterious effect on the healing of clean or infected wounds when the wound-bearing area was well supplied with blood.

The possibility that wounds are more likely to become infected in cases of diabetes than among the nondiabetic is another source of constant anxiety. It is generally believed that the incidence of wound infection is directly proportional to the height of the blood sugar level and the degree of glycosuria. The incidence of development of infection in clean operative wounds in relation to the blood sugar level in our cases of diabetes mellitus is shown in table 7. It will be seen that the wounds of the patients with the higher blood sugar levels became infected less frequently than those of the patients with the lower levels. These observations do not substantiate the popular opinion that high blood sugar levels of patients with diabetes mellitus tend to promote the development of infection. The presence of arterioscle-

that the nearer my patient is kept to the condition of a normal individual it will do him harm; I felt that it did him good.

DR. ROY D. McCLURE, Detroit: Like Dr. Joslin, I had always felt that an attempt should be made to reduce the blood sugar level before operation. The authors have been careful to state that this study should not cause any relaxation with regard to the preoperative and postoperative care of the diabetic surgical patient. Other factors present in the diabetic as well as in the nondiabetic patient are of undoubted significance in wound healing. Arteriosclerosis is well emphasized in the authors' tables. Acidosis, indicative of lack of dextrose utilization, is ominous. The untreated or malnourished person with diabetes may be deficient in vitamin C and plasma proteins, which appear to be important in wound healing. Fifty cases of wound disruption were recently studied by Dr. L. S. Fallis at the Henry Ford Hospital (*Surgery* 1:523 [April] 1937). Two of these patients, both women in their fifties convalescing from pelvic operations, had diabetes. The postoperative blood sugar of one patient was 192 and of the other 135. Wound disruption occurred despite adequate control of the diabetes. The first patient recovered after secondary suture. Obviously the second patient should have been treated conservatively by packing and strapping for she died shortly after an ill advised secondary wound suture. With our present practice of maintaining proper vitamin C and protein levels in the blood, such disruptions might not have occurred. The value of a high type of medical management has long been obvious. In a recent report from Bellevue Hospital (Standard, Samuel; Brandaleone, Harold, and Ralli, Elaine P.: *Surgical Results in the Treated and Untreated Diabetic Patient*, *THE JOURNAL*, Feb. 26, 1938, p. 627) the mortality from all types of operations was increased threefold in a group of nonclinic patients who had not been followed preoperatively. Following operation for complications of diabetes such as amputations and drainage of abscesses the postoperative course in my experience has not been as good as in the nondiabetic. But for elective surgery, if the diabetic patient has the advantage of adequate control of the diabetes and the maintenance of satisfactory protein, mineral, vitamin and water balance level the wound should heal as well as a comparable one in a nondiabetic patient.

DR. JAMES A. GREENE, Iowa City: It was not our purpose to discuss all the factors that are concerned in the healing of wounds. The purpose of our investigation, as we have stated, was to ascertain whether or not hyperglycemia and glycosuria were important factors in the healing of wounds in patients with diabetes mellitus. I think that delayed healing of wounds has been attributed frequently to the presence of hyperglycemia and glycosuria when as a matter of fact too much suture material has been employed or the tissues have been traumatized excessively. We do not advocate that a patient's diabetes should be neglected, and we made a statement to that effect in our report. The blood sugar estimations were obtained in our study two hours after a diabetic breakfast. The potential dextrose intake of these patients, except for the thirty-five who received large amounts, were from 110 to 170 Gm. daily. With regard to the use of insulin, our patients did not all receive insulin because the diabetes of some was not sufficiently severe. We adhere to the generally accepted indications for the use of insulin in our cases. The quantity of insulin was not correlated with delayed healing of wounds or with the incidence of infection, because we did not consider that it was significant in this study. The question raised regarding the arbitrary choice of 40 years as being the age when arteriosclerosis begins is a pertinent one. We recognized this difficulty, but from our data we arbitrarily chose this age. Perhaps it should be 50 or 60; we do not know; but we do not think that selection of either of the latter ages would materially alter the data that we have presented. With regard to the number of deaths, we did not include them because we were unable to ascertain whether or not a wound healed unless the patient lived for a sufficient length of time. There was a question from the floor regarding the frequency of evisceration or separation of abdominal wounds in diabetic patients. We have not observed this to occur any more frequently in diabetic than in nondiabetic patients.

AUTOMOBILE ACCIDENTS IN A RURAL AREA TRAVERSED BY A TRANS-CONTINENTAL HIGHWAY

JOHN H. POWERS, M.D.

COOPERSTOWN, N. Y.

An automobile accident in the open country is far more likely to result in serious injury and death than is a collision on the congested highways of a metropolitan district. In New York State during the past three years 8,022 persons were killed and 298,846 were injured by motor vehicles. Greater New York, with 55 per cent of the population of the state, was credited with 60 per cent of the accidents but only 30 per cent of the fatalities.¹ During these same three years rural

Chart 1.—Seasonal distribution of rural automobile accidents. The solid line represents the number of accidents each month, the broken line the number of patients injured. August is the most dangerous month.

New York, with 15 per cent of the population, was credited with 40 per cent of the fatal accidents.

The surgical staff of the Mary Imogene Bassett Hospital in Cooperstown, N. Y., is in a particularly favorable position for the study of automobile accidents in a rural area. The village is situated in the eastern central part of the state, 10 miles south of U. S. Route 20 a transcontinental highway from Boston and New York through Albany, Syracuse, Buffalo, Cleveland

From the Department of Surgery of the Mary Imogene Bassett Hospital.

Read before the joint meeting of the Section on Surgery, General and Abdominal, and the Section on Orthopedic Surgery at the Ninety-First Annual Session of the American Medical Association, New York, June 14, 1940.

and Chicago to the West. The hospital serves an area 50 miles in length along this highway and most of the persons seriously injured on this section of Route 20 are referred there for treatment.

The survey embraced by this report is based on the analysis of 492 accidents from which 712 patients were received at the hospital during the years 1930-1939 inclusive. It includes all the accidents in which a motor vehicle participated in any way other than those which

occurred in a public garage or on a farm. The material will be presented in graphic and tabular form in two sections: first, that which deals primarily with

Chart 2.—Weekly distribution of rural automobile accidents and number of persons injured thereby. Both are most common on Sunday.

the accidents and the number of persons hurt and, second, that which applies particularly to the patients and their injuries.

ANALYSIS OF ACCIDENTS

Seasonal, Weekly and Daily Distribution.—The distribution of these accidents throughout the year and the number of patients injured each month are presented

in chart 1. The heavy solid line represents the number of accidents, the broken line the number of patients. The sharp increase in the number of accidents and particularly in the number of persons injured on the open road during the summer is striking. The peak occurs in August, which is without question the most dangerous month of the year in the country,² both on the highway and on the farm.³ It is interesting that February and March, when the roads are in the worst possible condition, are the safest months for travel in rural areas.

In chart 2 is presented graphically the distribution of rural motor accidents by days throughout the week. The week end is extremely hazardous, particularly Sunday. Not only do most accidents occur on this day but more people are injured per accident. Monday and Thursday are comparatively safe.

Chart 3 represents the distribution of accidents throughout the day. It is apparent that the hours of late afternoon and early evening are the most dangerous. Traffic is heaviest during this portion of the day, drivers and pedestrians both are weary, and both are anxious to reach their destinations; excessive speed by the former and undue carelessness by the latter are common. The hours between 5 and 8 o'clock in the morning are safest for travel on the open road; drivers are rested and traffic is light.

Sixty per cent of these 492 accidents occurred during the hours of daylight, 33 per cent at night, and 7 per cent during the dusk of early morning or late afternoon.

Location of Accidents.—The location of sixty-four accidents in which seventy-seven patients were injured is unknown. Seventy-two per cent of the remaining accidents, in which 76.7 per cent of the patients were involved, occurred in the open country (table 1).⁴

Thirty-six and one-tenth per cent of the accidents took place on straight roads, 20.7 per cent on curves, 12.9 per cent at intersections and 10.1 per cent on hills. Many of the fifty-four accidents which occurred in driveways, yards, parking spaces and private garages

Chart 3.—Daily distribution of rural motor accidents and casualties. Both are most numerous between the hours of 4 and 8 p. m., least common between 5 and 8 o'clock in the morning.

2. Powers, John H.: Rural Medicine: Emergency Surgery in a Rural Hospital, Springfield, Ill., Charles C. Thomas, Publisher, 1939, pp. 51-63.
3. Powers, John H.: The Hazards of Farming, J. A. M. A. 113: 1375-1378 (Oct. 7) 1939.
4. In this and all subsequent tabulations the percentages have been computed from only those accidents about which the facts are known.

were due to passengers falling while entering or leaving cars or to drivers cranking or repairing their own machines (table 2).

Classification of Accidents.—Accidents in which the car was in motion but no collision occurred were most frequent. These were usually due to failure to make a turn by an operator who was driving too fast on a road with which he was unfamiliar (table 3). Collisions between motor vehicles, with fixed objects, and with pedestrians were next in order of frequency. These four types comprised 82.6 per cent of those accidents in which the data are known.

Types and Condition of Vehicles Involved.—Of 607 vehicles involved, 84.7 per cent were passenger cars (table 4); 82.2 per cent of the vehicles were apparently in good condition, a fact which strongly suggests that most of the accidents were due to carelessness of the driver; 3.4 per cent had defective tires, 2.8 per cent defective brakes, 2.4 per cent defective headlights and 1.9 per cent a defective steering mechanism (table 5).

Types of Collisions.—Head-on collisions and side-swipes were most common and comprised 73.5 per cent of the accidents. Angle and rear end collisions were less frequent. Two hundred and thirty patients were injured in 184 accidents in which no collision occurred.

Direction of Travel.—Eighty-two per cent of the patients were injured while traveling straight ahead. Surprisingly few mishaps occurred while turning in either direction or backing. The solution of the problem of automobile accidents on rural highways appears to rest largely with the operator who is driving forward.

Condition of Drivers, Roads and Weather.—Eighty-three per cent of the accidents happened while the vehicles were being operated by drivers who were apparently normal; 9.3 per cent were obviously intoxicated and 4.1 per cent were admittedly asleep.

Nearly 70 per cent of the accidents in which likewise 70 per cent of the patients were injured occurred in

of 5 and 8 o'clock in the morning. If the road is crooked with many intersections, the surface snowy or icy and the weather foggy, one may venture forth with a reasonable certainty of reaching one's destination. And, as a matter of fact, such is actually the case because under those conditions one will be forced to drive both slowly and carefully.

ANALYSIS OF INJURIES

Distribution by Age and Sex.—In the rural section of central New York embraced by this study both sexes were injured in automobile accidents very much more often between the ages of 15 and 24 inclusive than during any other decade of life. Throughout all ages males were involved with twice the frequency of females (chart 4).

Chart 4.—Graphic analysis by age and sex of persons injured in 492 automobile accidents.

TABLE 2.—Topographic Location of Accidents; Number and Percentage of Patients Injured in Each Locality

clear weather. Those which took place when the sky was overcast or during rain, fog and snow are listed in order of frequency in table 6.

Two thirds of the accidents in which the data are known happened on dry roads. Wet pavement was a contributory factor in 20.2 per cent; ice and snow were responsible for only a small proportion.

COMMENT

From the preceding facts it is apparent that persons who wish to comply with every precaution for safety on the rural highway should confine their driving to any Thursday in February or March between the hours

Position of Patients When Injured.—Drivers and passengers in the front seat were injured with equal frequency, passengers in the rear seat less than half as often. Pedestrians and cyclists comprised only a small proportion of the patients (table 3).

Classification of Injuries.—The 712 patients injured in these 492 accidents received 2,891 recorded injuries, classified according to the second edition of the Standard Classified Nomenclature of Disease. Fractures comprised the most common group; there were 655, of which seventy-four were compound. Lacerations, contusions and abrasions were next in the order of frequency. One hundred and eighty-four of the patients sustained concussion of the brain and 104 patients were in shock when they arrived at the hospital, an incidence of 26 per cent for the former and 15 per cent for the latter.

Topographic Location of Injuries.—Actually of more interest in a study of the injuries received in automobile accidents is their topographic distribution. The head and neck appear to be most susceptible and in this series were injured twice as frequently as any other portion of the body. Traumatic lesions of the shoulder and upper extremity, the trunk, and the hip and lower extremity were comparable to one another in numbers but less than half as common as injuries of the head and neck.

Period of Hospitalization.—As a result of these automobile accidents, 473 patients spent 9,580 days in the hospital, or a total period of 26.3 years. Eighty-nine patients were admitted for one day or less, and thirty-eight patients spent only two days. The average period of hospitalization was 20.3 days. Eighty patients made only one visit to the accident ward and then went on their way. The average number of visits was four.

Fatalities.—Thirty-five accidents were fatal. Twelve persons were killed immediately or died at the scene of the accident before the ambulance arrived; two of these are known to have sustained multiple compound fractures of the skull and face. Seven patients were moribund on admission to the hospital and survived for an average period of only thirty-five minutes after arrival. With the exception of one patient who succumbed to a pulmonary embolus 237 days after his accident, the duration of life in the remaining fifteen fatal cases was approximately six days.

The chief causes of death among the twenty-three patients who reached the hospital were fractures of the skull (seven simple and five compound) twelve cases, intracranial hemorrhage without fracture two cases,

fracture-dislocation of the spine (one cervical and one dorsal) two cases, crushing injury of chest with ruptures of multiple intrathoracic and intra-abdominal viscera one case, pulmonary embolism three cases and bronchopneumonia two cases.

The mortality rate for accidents on the open road was 8.5 per cent; in other words, one accident out of every twelve was fatal.

SUMMARY

During the years 1930-1939 inclusive 712 patients were treated for 2,891 injuries sustained in 492 automobile accidents in a rural area traversed by a trans-continental highway.

Such accidents occurred most frequently on week ends during the summer while driving straight ahead in

open country on dry roads in clear weather during the hours of daylight. Accidents in which no collision occurred were most frequent; head on collisions with other cars, with fixed objects and with pedestrians were common. Eighty-two per cent of the vehicles were apparently in good condition and 83 per cent of the drivers were apparently normal.

Males were involved twice as frequently as females. Serious injuries were common. Fractures comprised 22 per cent of the traumatic lesions; 26 per cent of the patients sustained concussion of the brain and 15 per cent were in shock. The head and neck were injured with twice the frequency of the trunk or either of the extremities.

The average period of hospitalization was 20.3 days and the average number of outpatient visits was four.

The mortality for accidents on the open road was 8.5 per cent.

CONCLUSION

Excessive speed and lack of acquaintance with the hazards of the open road are responsible for most automobile accidents on rural highways.

ABSTRACT OF DISCUSSION

DR. ALAN DEFOREST SMITH, New York: Within recent years the surgeon in rural communities has been confronted with a type of serious accident which is entirely new, and on the whole he has acquitted himself very creditably. This applies not only to hospitals and surgeons of the type of the staff at Mary Imogene Bassett Hospital, where, of course, one would expect these conditions to be well treated, but to the surgeons throughout the country. Partly responsible for this are the activities of the Committee on Fractures of the American Medical Association and of the American College of Surgeons, who have done so much work in raising the standard of the treatment of fractures throughout the country. This is

going to have an important bearing on our participation in the activities which are now going on abroad. When we get into the show this time, we shall find that we have many more surgeons who are well trained in treating fractures and serious injuries than we had last time. Indifference of the country as a whole to a situation which results in as many casualties yearly as we suffered from our participation in the World War is something that is hard to comprehend. Publication of statistics of this kind will help very much to bring about some reaction that will result in lessening these accidents. I hope that the statistics which Dr. Powers has will be made available to the public, because I think that there they will do the most good. One of his outstanding conclusions is that the reckless driver is chiefly responsible for the large number of accidents, but nevertheless the careful driver, the innocent man, is just as likely to suffer as a result of the reckless driving as the man who is himself responsible. One way we could diminish these accidents is to be more strict about revoking licenses of habitually careless and reckless drivers. The wisdom of issuing automobile licenses to minors is questionable, and that is borne out by the very large number of minors and young people who are involved in accidents. Any one who operates or owns an automobile should be compelled to insure himself against the economic consequences of the accidents that may occur. That applies not only to the people who are injured in the accident but also to the hospital and the doctor. The dictates of ordinary humanity demand that any doctor or any hospital shall take care of the patient who is injured in this way out in the country, and yet very often they are not recompensed in any way and they certainly should be. These people should be compelled to insure themselves against the consequences of these accidents.

DR. JOHN H. POWERS, Cooperstown, N. Y.: I have some statistics on one point which Dr. Smith brought out, namely the financial aspect of these accidents. At the Mary Imogene Bassett Hospital the staff is on a full time basis and all the bills are rendered and collected by the hospital. I was interested in discovering that 73 per cent of these 712 bills were paid in full, 12 per cent were paid in part and 15 per cent had to be written off completely. This 15 per cent represented a loss during the past ten years of approximately \$20,000. The other point I wish to emphasize is this: That by the most conservative estimate at least 95 per cent of all automobile accidents are due to recklessness and carelessness and are therefore preventable. The reduction of such accidents is a problem of national importance and is worthy of consideration by every surgeon who is fundamentally interested in the preventive aspect of his profession.

The Fluoroscope Replaces Mantoux Test.—In Puerto Rico the fluoroscope is our chief instrument for the early diagnosis of tuberculosis, while the pneumothorax apparatus constitutes our great recourse for controlling the spread of tubercle bacilli. We are using the fluoroscope as a substitute for the tuberculin test in the screening of suspicious cases of tuberculosis in adults and in children above the age of 12. We feel justified in this substitution because of the high proportion of tuberculin reactors above the age of 12. Over 80 per cent of children in the teens give positive reactions to the Mantoux test and we have concluded that it saves time, effort and money to fluoroscope every suspicious adolescent and adult on his first visit to the clinic rather than wait for the result of a tuberculin test which in over 80 per cent of the cases will be positive. . . . We take x-ray pictures with our fluoroscopes. They are 30 milliamper machines, and, where a radiographic equipment is not available, they are equipped with a timer and a cassette-stand which make possible the taking of x-ray plates with very simple adjustments. . . . The fluoroscopic work is done by specialists, but the medical officers of the public health units are being trained in its use. The number of fluoroscopic examinations made in the tuberculosis clinics of the Health Department during the fiscal year 1938-1939 was 71,220.—Pastor, J. Rodriguez: *The Fluoroscope and the Pneumothorax Apparatus as Tools for the Protection of the Public Health, Puerto Rico Health Bulletin*, September 1940.

THE EFFECT OF ALCOHOL ON VISION

AN EXPERIMENTAL INVESTIGATION

Z. WILLIAM COLSON, M.D.

BOSTON

These experiments were suggested by two personal subjective observations. The first was made rather startlingly in France over twenty years ago, following a champagne binge with a group of fellow aviators. When we left the café and started back to our billets my peripheral fields seemed to be markedly contracted, although central visual acuity appeared to be unaffected. I felt that I was looking through a pair of nonmagnifying binoculars. The second observation was made more recently. On leaving a brightly lighted cocktail party and stepping immediately into the dark, there seemed to be a definitely prolonged interval of my dark adaptation.

The first of these experiments were conducted in my office, but concern as to my local reputation necessitated transfer of the work to a research laboratory. I was particularly fortunate in my choice of "guinea pigs." Most of them were young professional men of higher than average intelligence and cooperation. Some were able to persuade their wives to be subjects for testing.

There were twenty-one subjects in all, and their ages ranged from 27 to 44. The average age was under 30.

A preliminary test was made of visual acuity, near vision, visual fields, color vision, muscle balance and dark adaptation. Each subject was then given a carefully measured 2 ounces of good quality rye or scotch with ginger ale or soda as he chose. Some preferred their drinks straight. The 2 ounce drinks and tests were repeated at half hour intervals until the subjects reached their gastric tolerance or in some other manner became incapacitated for further tests.

Since the intake was rapid enough to constitute fairly serious drinking, most of the tests were discontinued after 8 or 10 ounces, although one subject succeeded in consuming 20 ounces and was fully cooperative throughout the entire experiment.

The purpose of the tests was to determine the immediate visual effects of a few drinks as ordinarily consumed by the drinking public. There was no attempt to appraise the effects of chronic alcohol intoxication.

RESULTS OF TESTS

Visual Acuity.—Vision was taken by artificial illumination so that the light would remain the same throughout the experiments. In each case visual acuity in the preliminary test was 20/20—1 or 2, or better, with correction. Only three subjects showed any demonstrable reduction in visual acuity, and this reduction can be explained by the fact that in these cases the test was immediately followed by violent emesis.

Near Vision.—A Lebensohn near vision test chart was used at a distance of 14 inches. Most of the subjects at the outset had better than normal near vision, rating 1.2. There was no appreciable change after the alcohol intake.

Visual Fields.—A complete peripheral field was not done in these cases, because it was thought that the element of fatigue might enter as a definite factor. To simplify the procedure, in each case the fields were

taken on a standard perimeter, for one eye only, in the four cardinal directions. There was not the slightest variation in fields following alcohol intake.

Color Vision.—Color vision was tested by use of Ishihara charts under uniform artificial illumination. There was only one color blind individual found on the preliminary test, and his subsequent reading of the figures did not indicate any change in color vision. All others showed no change in color vision.

Dark Adaptation.—This was determined with an apparatus incorporating a graded wedge as the filter. The subject was preexposed to a bright light for three minutes before measurements were begun. Since I had no experience with this apparatus, Dr. David Cogan was kind enough to supervise the dark adaptation tests. From the standpoint of directness and simplicity, this test was the most difficult. It is a procedure which requires close attention and cooperation and, frequently repeated, may cause fatigue. If the tests had shown a slowing of dark adaptation, this could have been ascribed to lack of attention or delayed verbal response to light stimuli. In spite of these difficulties the curves, with one exception, came well within normal limits. The only subject who showed a prolongation of adaptation time was also the one who showed low dark

prism diopter, in one 1, in two 2 and in one 3. One subject had exophoria of 2 prism diopters. Hyperphoria in no case exceeded $\frac{1}{2}$ prism diopter. The tests were repeated during the experiment every half hour. There was practically no effect on the vertical muscle balance—only in two cases was it increased 1 prism diopter—but there was a gradually increasing esophoria in each case, which in two cases reached the stage of actual strabismus with diplopia. In one of the latter cases the esophoria increased from 3 to 8 prism diopters, in the other case from 0 to 3.5. The minimum change in muscle balance was 2 prism diopters (two cases), the maximum was 11 (one case). In the latter the change was from 2 prism diopters exophoria to 9 prism diopters of esophoria, and it is interesting to note that there was no diplopia in this case, and that the patient passed through a stage of orthophoria.

Duction tests were made on three subjects. These were made in the usual manner, a variable prism and a distant fixation light being employed. The results obtained are shown in the accompanying table.

According to the conventional notation, the abduction in all cases was reduced. But duction power can be determined only by allowing for the muscle balance at the time of the test. Making this allowance, the real abduction was very little affected—in A it was actually increased. The real adduction was decreased in each case, in C markedly.

As pointed out by Verhoeff,¹ it is probable that the conventional tests for adduction do not reveal the involuntary adduction (analogous to sursumduction) but chiefly the voluntary convergence power.

In view of the fact that alcohol has little effect on real abduction, it is probable that it depresses the convergence center and has little effect on the involuntary adduction.

It is evident that the diplopia which alcohol produces in normal subjects is due to an increasing esophoria which finally cannot be overcome by the abduction, although this remains almost unchanged. Since alcohol is known to be a depressant, it is not surprising that the real adduction should be reduced, but in view of the latter fact it is indeed surprising that esophoria rather than exophoria should develop.

While no depth perception tests as such were done, it seems probable that the esophoria noted would have a definite effect on depth perception. It would seem that one who drinks frequently would be more likely to educate oneself to allow for changes in distance values under these varying conditions of muscle balance than would the very occasional drinker. It was suggested to me by Dr. Verhoeff that the esophoria would affect chiefly the judgment of absolute distance and have no important effect on that of relative depth.

CONCLUSIONS

Visual tests following the consumption of alcohol by twenty-one normal individuals showed no diminution of visual acuity, visual fields or color vision.

Except in one case, in which the dark adaptation was already abnormally low, conventional tests for dark adaptation showed that alcohol had no appreciable effect on the shape of the recovery curve.

Tests of muscle balance showed no tendency to hyperphoria, but all subjects showed a gradually increasing esophoria. Two subjects progressed to actual convergent strabismus with diplopia in the latter part

Lateral Duction Tests Before and After Drinking

	Phoria	Conventional Abduction	Real Abduction	Conventional Adduction	Real Adduction

adaptation in the preliminary test. Alcohol appeared further to increase slightly the time interval of adaptation in his case.

These tests suggest that alcohol has no effect on dark adaptation when one's margin of safety is high, but it may have a definite effect when through vitamin A deficiency or severe fatigue the reserve is low. Conceivably, alcohol could lower dark adaptation either by hastening the combustion of visual purple or by retarding its formation.

In spite of the fact that the dark adaptation tests employed did not show anything conclusive, I believe that further tests in which the visual purple is more completely broken down and in which a shorter interval is allowed for a first reading should be done. They may show whether a persistence of light scotoma or retardation of perception in the dark may occur—as in seeing objects on the road after being subjected to the glare of oncoming headlights. Until such tests are devised and are sufficiently conclusive, one should not assume that there is no momentary involvement of dark adaptation after the consumption of alcohol. While the tests done in this series show no appreciable change in shape of the recovery curve, there may have been changes in the first portion of the curve which the technic employed was not quick enough to catch. Such retardation, if present, would be extremely hazardous in night driving.

Muscle Balance.—This was determined by the use of a Maddox rod and variable prism. The results of all preliminary tests were well within normal limits—in sixteen subjects there was esophoria of less than 1

1. Verhoeff, F. H.: Hyperphoria Tests Based on a New Principle. Arch. Ophth. 22: 743-759 (Nov.) 1939.

of the tests. One subject had definite exophoria at the outset and therefore passed through a stage of orthophoria before becoming esophoric.

The diplopia that results from alcohol is associated with a reduction, not with an increase, in convergence power and is dependent on the development of esophoria too great to be overcome by the abduction power, although this remains unchanged.

CHRONIC FRIEDLÄNDER INFECTIONS OF THE LUNGS

REPORT OF SEVENTEEN CASES AND OBSERVATIONS
ON THERAPY WITH SULFAPYRIDINE
AND SULFANILAMIDE

SAUL SOLOMON, M.D.
NEW YORK

In a recent communication I reported a series of cases of acute Friedländer pneumonia, giving reasons for considering this disease as a distinct and primary form of pneumonia.¹ Before proceeding to a description of chronic lung infections caused by the Friedländer bacillus (*Bacillus mucosus capsulatus*), the essential features of the acute disease will be reviewed briefly.

In common with other pneumonias, the onset is usually sudden, with chills, fever, cough and pain. The clinical course, however, is fulminating and the mortality extremely high. Certain other features serve further to distinguish Friedländer pneumonia from other forms:

1. Pneumonia due to the Friedländer bacillus comprises from 1 to 3 per cent of all pneumonias and occurs almost exclusively in the later decades of life with a considerable preponderance of males over females. It almost never occurs in children.

2. Hemoptysis is a frequent initial symptom in this disease. Herpes is uncommon, but jaundice is a rather frequent accompaniment.

3. Though the lesion is lobar in distribution, the classic signs of consolidation such as bronchial breathing and pectoriloquy are absent in about half the cases. When one observes the heavy, soggy lung at necropsy, the dulness and suppressed breath sounds are readily explained. Involvement of the upper lobe and involvement of more than one lobe are frequent.

4. The temperature is less regular, and low grade fever is more common than in pneumococcal pneumonia.

5. The gross appearance of the sputum generally is characteristic. It is that of a brick-red homogeneous emulsion of blood and mucus, in contrast to the rusty taffy-like sputum of pneumococcal pneumonia. A direct smear of the sputum stained by Gram's method will usually show a predominance of the typical gram-negative bacilli surrounded by a clearer zone representing the capsule. Inoculation of the sputum into the mouse, an animal extremely susceptible to this organism, will invariably confirm the diagnosis.

6. Pure cultures of the Friedländer bacillus are obtained from the sputum, from the lung juice and frequently from the blood cultures.

7. Leukopenia and monocytosis with a shift to the left in the Schilling index are frequent, leukocytosis appearing in the complicated cases.

8. Bacteremia is more frequent but is quantitatively less intense than in pneumococcal pneumonia. The mortality rate is apparently little affected by the absence of bacteremia.

9. Abscess formation is the most frequent complication, empyema and meningitis are less common. The Friedländer bacillus may readily be cultivated from the pus and spinal fluid in such cases.

10. At necropsy the involved lobes are marked chiefly by some degree of softening and necrosis of the lung with the presence of a characteristic dirty, slimy exudate on the cut surface. Culture of the lung, if necropsy is performed soon after death, yields the Friedländer bacillus, and on microscopic section the organisms may be seen as gram-negative encapsulated rods lying free in the alveoli and within the cells.

From the foregoing considerations it will be seen that usually acute Friedländer pneumonia terminates fatally within a relatively short time. With the exception of the very few who recover completely, the surviving patients pass into the chronic stage. Observations on this latter group of lung infections known as chronic Friedländer pneumonia will now be presented.

In contrast to the fulminating and highly fatal character of the acute disease, the chronic Friedländer lung infections run a protracted and relatively benign course, months or years in duration. The Friedländer bacillus shows a marked tendency to cause nonputrid pulmonary necrosis, though it never leads to caseation. Hence, because of the presence of cavities in the lung and because of the frequent upper lobe involvement, the chronic form of the disease is very commonly mistaken for pulmonary tuberculosis.

Although the time element is important in separating the cases into acute and chronic groups, nevertheless, it is difficult to draw a distinct dividing line. Bullowa, Chess and Friedman² report that 75 per cent of their patients with acute Friedländer pneumonia died within eight days and that the average clinical course was less than two weeks. The experience of other authors is similar. My own acute cases followed a course lasting from two to sixteen days. Arbitrarily, therefore, a time limit of four weeks may be allowed beyond which a case should be considered as falling into the chronic group.

For the sake of completeness, it should be mentioned that the Friedländer bacillus not uncommonly is encountered as a secondary invader in the course of other pulmonary infections.³ However, because of limitations of space, such cases are purposely omitted from this presentation. For the same reason, there will be no discussion here of the important and interesting extrapulmonary infections caused by the Friedländer bacillus.

LITERATURE

The importance of the Friedländer bacillus as a cause of chronic lung infections is beginning to receive greater recognition. Recently, Amberson has emphasized that in suspected cases of chronic pulmonary tuberculosis when repeated examinations of sputum reveal no tubercle bacilli, it is important to search for the Friedländer bacillus as a possible causal agent.⁴ Nevertheless, the number of chronic Friedländer lung infections reported in the literature is small.

Read before the Montreal Clinical Society, Montreal, Canada, Nov. 24, 1939.

Owing to lack of space, figures 8, 9, 10, 15, 16 and 17 have been omitted; they are included in the reprints.

From the Fourth Medical Division of Bellevue Hospital, Dr. Charles H. Nammack, director, and the Dr. Simon Baruch Foundation for Research.

Four of the cases presented here were observed in the wards of the Tuberculosis Service, Dr. J. Burns Amberson, director. Certain of the laboratory studies in these four cases and one other were done as part of a study of sulfapyridine therapy conducted by the Bellevue Hospital Pneumonia Investigation.

1. Solomon, Saul: Primary Friedländer Pneumonia, *J. A. M. A.* **108**: 937 (March 20) 1937.

One of the earliest cases was reported by Sisson and Thompson.⁵ This concerned a 31 year old man who developed a bronchopleural fistula and a Friedländer bacillus empyema, making an apparently complete recovery in three months. Belk³ in 1926 reported three cases of chronic pulmonary suppuration due to the Friedländer bacillus and pointed out the possibility of confusion with pulmonary tuberculosis. Stoichitz and Jonnesco⁶ in 1933 observed a patient with lung abscess following tonsillectomy who died after thirty-six days, the blood culture showing Friedländer's bacillus. In 1930 Crohn⁷ reported the case of a man with Friedländer pneumonia and bacteremia who died after an illness of two months, showing at autopsy an ulcerative polypoid endocarditis of the mitral valve with septic infarcts in the spleen, kidneys and intestine.

Sweany, Stadnichenko and Henrichsen⁸ had the opportunity to study one case for twenty-eight months. The patient was a 45 year old man whose illness began suddenly with pneumonia of the right upper lobe. The lesion subsequently spread to the left upper lobe and resulted in bilateral upper lobe cavities closely simulating tuberculosis. The case closely parallels that described by Westermarck⁹ which began as an acute pneumonia but resulted in thin-walled abscesses in both upper lobes, death occurring after seven months of illness. Schapper¹⁰ in 1931 described a similar case in which death followed operation for lung abscess after an illness of three months. Stengel and his associates¹¹ have reported the largest series to date (four cases) and in several publications have outlined the characteristic roentgenologic picture.

INCIDENCE

It is difficult to estimate the incidence of chronic Friedländer pneumonia. For comparative purposes, it may be noted that it is less common than acute Friedländer pneumonia, which in turn comprises approximately from 1 to 3 per cent of all adult cases of pneumonia. It is probable, however, that the disease is more common than is generally supposed since, as stated, this condition is frequently mistaken for other chronic lung diseases.¹²

Chronic Friedländer pneumonia occurs chiefly in the later decades of life. The patients in this series ranged in age from 34 to 69 years, the average age being 49 years. No case has yet been observed in childhood. The disease is more frequent in males, twelve of the patients in this series being males and five females. All the patients were white. The seasonal incidence is not striking. Ten cases occurred in the six inclement months from November to April inclusive and only seven in the remaining six months.

Alcoholism as a predisposing factor was recorded in nine cases. The association between cirrhosis of the liver and Friedländer infection is not uncommon. Occupation apparently plays no role. In two of the cases the pneumonia followed submersion (drowning) and parturition respectively.

CLINICAL COURSE

With only three exceptions all the cases began acutely with a combination of the following symptoms: general malaise, chills, fever, pleuritic pain and cough. Gastro-intestinal symptoms occurred in only three cases and in one of them was due to an associated hepatic condition.

The temperature was quite irregular, ranging from normal to 105 F. In several cases in which suppuration was severe, there were marked diurnal variations in the fever. In some instances, varying periods of normal temperature alternated with febrile episodes. The temperature came down by lysis in seven of the nonfatal cases, on the average about the forty-fifth day of illness, though low grade pyrexia frequently persisted afterward for weeks or months. In three of the four cases treated with sulfapyridine, the fever dropped sharply within twenty-four to seventy-two hours and in one instance the fever came down slowly in ten days. The only patient who received sulfanilamide had a lysis after seven days of treatment. In the four fatal cases, death occurred after thirty-six days, forty-three days, thirty days and fourteen months respectively.

For the purpose of convenience the entire illness may be divided into two phases: first the acute stage, where there ensues in the majority of cases an apurid necrosis of the lung and quite frequently pleural effusion, whether purulent or serous. Second, if the patient survives, there occurs the stage of chronic pulmonary suppuration with one or more thin-walled abscesses, bronchiectasis or fibrosis or a combination of these processes, which so far as I know may persist indefinitely with exacerbations and remissions. Death may occur at any point in the clinical course but occasionally, if the lesion is not too extensive, there may be apparently complete resolution.

During the early stages, most of the patients were severely ill and prostrated and were in effect suffering from acute Friedländer pneumonia. After a varying period, the illness assumed the features of chronicity, lasting anywhere from one month to more than three years as far as could be determined. Moreover, there were individuals who recovered and were discharged with incomplete clearing of the lungs only to be readmitted after a lapse of months with a recurrence or an exacerbation of the disease. It should be emphasized, therefore, since most of the illnesses began as pneumonia, that patients who have recovered from acute Friedländer pneumonia should not be dismissed from observation too soon because of the strong possibility of the development of chronic lung changes.

Herpes was noted in only one case. No petechiae or other cutaneous lesions were seen. Jaundice was noted in only two cases. In one it was associated with a subdiaphragmatic abscess, in the other with cirrhosis of the liver. None of the patients showed clubbing of the digits.

While no extensive immunity studies were carried out, an attempt was made in six nonfatal cases to determine at different intervals in the course of the disease the presence of immune bodies as exemplified by agglu-

12. Since this article was completed, I have seen six additional cases which are not included in this report but which are similar in all important respects to the cases in this series.

tinins and capsule-swelling substances.¹³ In general they were found to appear in the blood in the recovery phase during the first weeks of illness and to persist for from one to three weeks or longer.

Only four of the seventeen patients in this series died, a mortality of 23.5 per cent as compared with 97 per cent in the acute group. However, these statistics are not final since several patients have not returned for observation after leaving the hospital. Four of the patients have not yet been discharged, though it appears

As shown in table 1, upper lobe lesions occurred in ten cases. In four other cases, the upper lobes were involved in conjunction with other lobes. Thus in fourteen cases (82 per cent) there was upper lobe involvement. Multiple lobe involvement occurred in five cases (30 per cent), although in only two cases of this series was there infection of both lungs.

SPUTUM

As seen from table 2, bloody sputum or gross hemoptysis was noted in five cases. In six others the

likely that they will recover. Five others have returned to their usual mode of life and are followed at intervals in the clinic.

DISTRIBUTION OF THE PULMONARY LESION

In only one case was the lesion bronchopneumonic while in sixteen it was predominantly lobar or confluent lobular in distribution. In several of these latter cases, however, in addition to the lobar lesion there was either simultaneous or subsequent patchy infection of other areas.

13. These tests were carried out with the technical assistance of Miss Ruth Egan.

sputum was at the onset the characteristic homogeneous, brick-red mixture of blood and mucus which has been described in the introductory paragraphs. It is important to note that the character of the sputum is not constant but will change during the course of the disease. It is generally bloody and mucoid during the early stages; later it becomes mucopurulent and turns either green or yellow. Hemoptysis may occur at any stage of the illness, that during the early phases being due to pulmonary congestion and necrosis and later in the disease to lung abscess or bronchiectasis. It is not usual for the sputum to become foul,

and such an occurrence is indicative of secondary invasion by anaerobes.

If a direct smear of the sputum is stained by Gram's method, it is frequently possible to recognize the predominant organism as large gram-negative rods sur-

For key to abbreviations see table 1.

rounded by a refractile zone representing the capsule. After mouse passage or culture in laboratory mediums there generally occurs a change in the morphology, and the rods become shorter and even coccoid.

Analysis of table 2 shows clearly that during the early stages of the infection the Friedländer organism will usually be found in pure culture in the sputum, though in some instances it may become contaminated with other bacteria from the upper respiratory tract.

The most certain method of identifying the organism is to inoculate the peritoneal cavity of a white mouse with a saline suspension of the sputum and examine bacteriologically the peritoneal fluid and the heart's blood or the brain of the mouse within twelve to twenty-four hours. Furthermore, if a loopful of sputum is streaked on a blood agar plate, the great majority of the colonies will prove to be Friedländer bacilli. By either method, the Friedländer bacillus can thus be recovered in pure culture and the organism may be further identified by agglutination tests or by the capsule-swelling method as belonging to group A, B or C. In all but one of the cases, positive evidence was obtained by discovery of the Friedländer bacillus in the sputum on one or more occasions and in nine of the cases the organism was typed. In seven of these instances a type A bacillus was found, in one a type B organism was isolated, and in still another case type C was the responsible organism.

It should be emphasized here that in the later stages of the illness, if abscess or bronchiectasis becomes established in the involved lung, these mechanical defects offer a nidus for secondary infection. Also, owing perhaps to immune processes, there is frequently a diminution in the number and virulence of the Friedländer bacilli, which become overgrown with secondary invaders. The remaining Friedländer organisms may become so attenuated that they are not virulent for mice, and only culture on an agar pour plate will reveal their presence.

BACTERIOLOGY OF LUNG FLUID, PLEURAL FLUID AND SPUTUM OBTAINED BY BRONCHOSCOPY

Since the sputum may become contaminated by organisms from the upper respiratory tract, it is desirable, whenever possible, to secure material for culture from other sources. Lung suction was done in one patient. The Friedländer bacillus type A was recovered on three occasions from the lung fluid of this individual during a period of several months. On eight other patients thoracentesis was done because the clinical observations suggested fluid. In four cases thoracentesis yielded pus which was found to contain the Friedländer bacillus. In the four other cases a nonpurulent pleural effusion was withdrawn which in two of the cases contained the Friedländer organism and in the other two was sterile.

Bronchoscopy was performed on three patients. Culture of the sputum from the bronchus of the involved lobe yielded the Friedländer bacillus in each instance.

BACTEREMIA AND ITS RELATION TO MORTALITY

Blood cultures were made for thirteen patients of this series, several cultures usually being made in each case. As shown in table 3, only four patients had bacteremia; the blood stream of three of these was only mildly invaded and quickly became sterile, in one instance after sulfapyridine therapy and in another after the use of sulfanilamide. In one other nonfatal case as many as 25 colonies per cubic centimeter of blood were found. However, in this instance, the disease was due to a type C organism which apparently is less virulent than the more common type A.

Analysis of the data contained in table 3 discloses first a low mortality in the entire group of chronic Friedländer lung infections—23.5 per cent as compared with the 97 per cent mortality noted in the acute cases. Second, bacteremia is relatively infrequent in chronic Friedländer pneumonia, occurring in 31 per cent of

the cases as compared with 70 per cent in the acute group. Third, as in acute Friedländer pneumonia, the blood stream invasion is generally mild and does not apparently play an important role as a cause of death. The recent case report,¹⁴ therefore, of a recovery from Friedländer bacteremia without pneumonia following sulfapyridine therapy should not be hailed with too great enthusiasm.

BLOOD CELL CHANGES

White cell counts were done in sixteen cases, in twelve of which serial determinations were made. The count ranged from 4,200 to 33,800. In the majority of the cases there was a moderate degree of leukocytosis during the acute phases of the illness. The highest count (33,800) was reached in a case complicated by both lung abscess and empyema. In only three cases was there a true leukopenia, which contrasts with the data in the previously reported acute group, in which leukopenia occurred at some stage during the period of observation in about one half of the cases. The percentage of polymorphonuclears varied from 32 to 96 per cent of the total, being usually elevated with a shift to the left in the Schilling index during the acute phase of the illness. The monocytes ranged from 0 to 20 per cent. There were five cases (31 per cent) in which the monocytes reached 6 per cent or more during the period of observation.

COMPLICATIONS

Complications were frequent, in fact almost universal, in this series and were in the main limited to the chest. Lung abscess was demonstrated roentgenologically in ten cases, death occurring in two of these during the period of observation. In four instances the diagnosis was confirmed at operation and in one at necropsy. Abscess formation was generally marked by a change in the character of the sputum, which became copious and mucopurulent but not, as a rule, foul.

In three of the cases of lung abscess there developed an encapsulated empyema from which in each instance the Friedländer bacillus was isolated in pure culture on one or more occasions. Empyema occurred in one other case, unassociated with lung abscess.

The pus in the empyema cases was thick, yellowish green or creamy; it contained a predominance of polymorphonuclear leukocytes and when first discovered yielded Friedländer bacilli in pure culture. Subsequently, in two of the cases other organisms were found, the assumption being that they were secondary invaders.

Pleural effusions of a serous nature were noted in four cases. In two of these the effusions were large, 1,500 cc. and 750 cc. of fluid respectively being removed by thoracentesis and in both cases yielding the Friedländer organism in pure culture. In the third case, the serous effusion was encapsulated and the fluid sterile. However, this patient showed lung abscess and loculated empyema in both of which the Friedländer bacillus was demonstrated. In the fourth case the effusion occurred two months after the onset of illness and was small in amount and sterile.

A rather frequent sequela was pulmonary fibrosis and delayed resolution, which was observed in four cases. In one instance this was associated with a purulent bronchiectasis as demonstrated in bronchograms (figs. 6 and 7).

14. Meyer, K. A., and Amtman, Leo: Treatment of Friedländer's Septicemia by Sulfapyridine with Recovery, *J. A. M. A.* 113: 1641 (Oct. 28) 1939.

Severe hemoptysis was observed in only one case. Delirium occurred in only one case and was attributed to associated chronic alcoholism. Meningitis did not occur in this series. The unusual complication of axillary vein phlebitis occurred in two patients, being in both instances associated with abscess and encapsulated empyema on the same side. The phlebitis subsided in both cases after sulfapyridine therapy and surgical drainage of the chest, but in one case it was followed by an acute inflammatory arthritis of the wrist on the same side.

X-RAY STUDIES

It was possible in most of the cases of this series to obtain serial roentgenograms at various stages of the disease. The earliest changes noted are those of lobar or confluent lobular consolidation, followed in the majority of cases by abscess formation or by bronchiectasis. Pleural effusion either serous or purulent is common. There is frequently a considerable degree of pulmonary fibrosis as evidenced by x-rays. Lung abscesses, once established, tend to persist indefinitely if a fatal issue is avoided. Complete clearing, however, does occasionally occur.

Kornblum and his associates¹¹ describe four phases, as observed by serial roentgenograms: first, the stage

TABLE 3.—*Relation of Bacteremia to Mortality*

of primary bronchopneumonia; second, coalescence to form a pseudo lobar pneumonia; third, pulmonary necrosis, and finally the formation of numerous irregular cavities of various sizes. While such a classification has the merit of convenience, it is by no means true that chronic Friedländer pneumonias necessarily follow this course. On the contrary, in many instances the early manifestations are those of a massive dense shadow in the involved lung, frequently suggestive of encapsulated fluid. Moreover, abscess formation is not universal, since in certain cases of acute Friedländer pneumonia there is recovery with complete clearing of the lesion as shown by roentgenogram. In the majority, however, abscesses, bronchiectasis or fibrosis develops and these latter changes may persist for years or even for the duration of the patient's life. It is not my impression that the roentgenologic changes at any stage in the course of this disease are by themselves pathognomonic, though serial roentgenograms when considered in conjunction with the history and clinical course are most helpful in pointing to the diagnosis.

DIFFERENTIAL DIAGNOSIS

During the acute stage, the disease resembles pneumococcal pneumonia with the exception that in a certain percentage of cases the sputum has the characteristics of the acute Friedländer pneumonia. There are other clinical differences, already enumerated, and careful bacteriologic study will conclusively distinguish this disease from the pneumococcal infections.

It is during the succeeding phases that an error is most likely to be made. If pulmonary suppuration

occurs and is followed by secondary anaerobic infection with the production of foul sputum, it usually leads to a diagnosis of putrid lung abscess. However, if the sputum is cultured by streaking on a blood agar plate or by mouse inoculation, it is possible correctly to reconstruct the pathogenesis of the illness. Fortunately, in most instances the pulmonary necrosis is nonputrid.

Perhaps the commonest mistake is to diagnose the condition as chronic pulmonary tuberculosis because of the bloody mucopurulent sputum and the x-ray appearance of an upper lobe lesion associated with cavities and pulmonary fibrosis with or without a certain degree of lung shrinkage. However, repeated examinations of concentrated specimens of sputum and guinea pig inoculation will not show tubercle bacilli. By detailed cultural analysis, it is generally possible to isolate the Friedländer organism in pure or mixed culture. In some cases the original organism may disappear, leaving behind merely cavities in one or more lobes. If there are no bacteriologic studies preceding this stage, it is impossible to prove the diagnosis. I have the impression that this is not uncommon.

In some instances, the disease has been mistaken for carcinoma of the bronchus. Bronchoscopic biopsy in such cases will reveal only granulation tissue, and further study of the sputum and the clinical course will demonstrate the true nature of the disease.

TREATMENT

Treatment of the acute illness was in most of the cases symptomatic, specific horse serum not being employed because of the disappointing results observed with its use in the acute disease.¹ Bed rest, expectorants and general nursing care constituted the main features of therapy. Complications were treated by the necessary special measures.

Of the ten patients with lung abscess, three were treated symptomatically with postural drainage and bronchoscopy. Two patients recovered and the third died. Two patients with lung abscess who received sulfapyridine and one who received sulfanilamide recovered. Four other patients with lung abscess, in three instances complicated by encapsulated empyema, were treated surgically. Two of them were given sulfapyridine and the lesions are still draining but the patients appear to be recovering. Of the two who did not receive sulfapyridine one died and the other still has a draining fistula.

Empyema occurred in four cases with the development of thick yellow pus which required thoracotomy with rib resection. Two of the patients, as already noted, were treated with sulfapyridine and recovered, and the two other patients died.

While each case should be considered on its merits, it is my impression that surgical drainage of Friedländer lung abscesses should be avoided whenever possible. The abscess will generally drain adequately through the bronchus, particularly if aided by postural drainage and repeated bronchoscopies. Moreover, in most cases the results with surgical therapy are not striking and the resultant fistulas seem to drain interminably.

As may be gathered from foregoing statements, four of the patients were treated with sulfapyridine. Two Gm. of the drug was given at the start, followed by 1 Gm. every four hours till improvement was noted. All four of these patients recovered, one of them despite the presence of bacteremia. It is difficult to evaluate the effectiveness of sulfapyridine with such a small number

of cases, nor are there, to the best of my knowledge, any previous reports in the literature dealing with the use of sulfapyridine in this disease. The mortality rate in the untreated group was 31 per cent while none of the treated patients died, which in itself is encouraging. It would appear that the drug was most useful in permitting survival during the acute stage. There was, however, little other evident effect on the clinical course, since in three of the cases during the course of therapy suppuration and abscess formation occurred.¹⁵ In the fourth, this process was already well established when treatment was begun. While the results with sulfapyridine are still inconclusive, one should, nevertheless, for the present accept the remedy as the most promising yet advanced for the treatment of this disease.

One bacteremic patient was treated with sulfanilamide, a total of 120 Gm. being administered. This man recovered and was discharged though he too had multiple lung abscesses.

REPORT OF CASES

The following six protocols are selected as best illustrating the salient features of the disease:

CASE 1.—G. A., a white man aged 48, became ill suddenly, being awakened by a sharp pain in the left chest with chills, fever and bloody sputum. When admitted to Bellevue Hospital,

March 11, 1934, on the seventeenth day of disease, he appeared poorly nourished, dyspneic and acutely ill with consolidation of the left upper lobe. During the first ten days, several examinations of the sputum showed pure Friedländer bacilli type A, no tubercle bacilli being found. The sputum, at first mucoid and bloody, became abundant, foul and purulent by the twenty-ninth day owing to secondary anaerobic infection. The sputum retained this character

Fig. 1 (case 1).—The thirty-fourth day of disease, multiple abscesses of the left upper lobe with spread of infection to the right upper lobe.

throughout the remainder of the illness, with the quantity varying from 20 to 100 cc. in twenty-four hours.

Fluoroscopic study on the thirtieth day showed a lung abscess in the left upper lobe with a shifting fluid level. X-ray films four days later (fig. 1) showed multiple abscesses and a spread of the infection to the right upper lobe. The patient was examined by bronchoscope on the thirty-second day, and a large plug of thick foul mucopus was aspirated from the bronchus of the left upper lobe. Blood cultures were repeatedly sterile. The white blood cell count on the twenty-fifth day was 7,850 with 68 per cent polymorphonuclears and 32 per cent lymphocytes, and on the thirty-second day it was 4,700 with 32 per cent polymorphonuclears and 68 per cent lymphocytes. The temperature was irregular, ranging from 100 to 104 F. with marked diurnal variations in the last week of illness. Treatment consisted of postural drainage, intravenous guaicol therapy and bronchoscopic procedure, but the patient failed to respond, death occurring on the thirty-sixth day of illness.

At autopsy the left upper lobe was gray and consolidated, containing a large multiloculated abscess 8 cm. in diameter and

15. Recently a woman aged 72 with Friedländer pneumonia of the right upper lobe was treated with sulfapyridine by Dr. H. K. Ensworth in the service of Dr. Asa Lincoln at Bellevue Hospital and made a complete recovery within ten days with no sequelae. Possibly the fact that treatment was begun only a few hours after onset contributed to her unusually favorable response.

partly full of green viscid pus, the wall being gray, necrotic and fibrous. The right upper lobe was consolidated, and both lower lobes were congested.

CASE 2.—J. S., a white man aged 72, awakened from sleep the morning before admission with fever, general malaise and cough with bloody phlegm. He was admitted Oct. 25, 1937, appearing acutely ill, dyspneic and cyanotic, with a fever of 103 F. and consolidation of the right upper lobe. A roentgeno-

gram again acutely ill and dyspneic with a temperature of 103 F. and the classic signs of consolidation. On the following day the temperature fell to 99 F. A roentgenogram taken February 3 (fig. 4) showed consolidation of the right upper lobe.

The sputum typing on two occasions showed a predominance of Friedländer bacilli type A, and a few pneumococci. Numerous examinations of concentrated specimens of sputum yielded no tubercle bacilli. Lung section was performed February 11,

Fig. 2 (case 2).—Oct. 27, 1937, the second day of illness, Friedländer pneumonia in the right upper lobe.

Fig. 3 (case 2).—November 22, showing considerable resolution.

Fig. 4 (case 2).—Feb. 3, 1938, fresh consolidation in the right upper lobe.

gram (fig. 2) taken October 27 showed irregular consolidation confined to the right upper lobe, as well as old pleural thickening and emphysema.

The sputum was thick, brown and mucoid, and a direct smear showed many gram-negative encapsulated bacilli (Friedländer). The sputum typing yielded Friedländer bacilli type A, and the sputum culture showed a predominance of Friedländer organisms with a few unclassified pneumococci. Lung suction with culture of the lung fluid yielded Friedländer bacilli type A in pure culture.

yielding the Friedländer bacillus type A and a few contaminants (staphylococci).

Serial x-ray studies, of which figure 5 (March 2) is representative, showed progressive clearing of the lesion. Because of continued expectoration of considerable mucopurulent sputum a bronchogram was made, which showed a normal bronchial tree in the lower lobes. However, the bronchogram of the right upper lobe (figs. 6 and 7) showed bronchiectasis in the posterior portion of the right upper lobe. The patient was discharged April 15, with residual signs of infiltration in the

Fig. 5 (case 2).—March 2, partial resolution.

Figure 6.

Figure 7.

Figs. 6 and 7 (case 2).—March 8, bronchogram demonstrating bronchiectasis of the right upper lobe.

The patient was treated symptomatically and in three days the temperature fell by crisis. However, he continued to raise a green, mucopurulent sputum which remained negative for tubercle bacilli and still contained the Friedländer bacillus as the predominant organism. A roentgenogram taken November 22 (fig. 3) showed considerable clearing of the pneumonia. He was discharged December 1 to a convalescent home, although his lesion had not completely resolved.

He was readmitted Feb. 3, 1938, stating that in the interval he had been troubled by dull pain in the right side of the chest and cough with copious green sputum. Three days before his readmission he had chills and a sudden rise in fever. He was

right upper lobe and is still under observation in the chest clinic of the Fourth Medical Division of Bellevue Hospital. There is dullness over the right upper lobe but no rales. A roentgenogram made Nov. 3, 1939 (fig. 8), shows infiltration and residual iodized oil in the right upper lobe. He raises several ounces daily of thick mucopurulent sputum which is consistently negative for tubercle bacilli. Culture of the sputum on several occasions has yielded Friedländer bacilli type A mixed with other organisms (streptococci, staphylococci and diphtheroids). The symptoms mentioned, however, are not troublesome and he is able to continue in his occupation as an orderly.

CASE 3.—M. C., a white man aged 50, had a respiratory infection in May 1938. A routine roentgenogram (fig. 9) in the clinic showed no disease of the lungs.

June 10, 1939, he had a sudden sharp pain in the right side of the chest, chills and fever, and raised mucoid bloody sputum. He was admitted June 18, appearing acutely ill with a fever of 103 F. There was dullness in the upper third of the right side of the chest with suppressed breath sounds and a few fine moist rales. The rest of the examination was negative except for moderate enlargement of the liver, attributed to fatty degeneration because of the history of alcoholism. June 19 a roentgenogram (fig. 10) showed a large wedge-shaped area of consolidation in the midzone of the right lung, and the lateral view showed this lesion to be limited to the right upper lobe.

The sputum was thick, brown and mucoid and when cultured showed a preponderance of Friedländer bacilli with also some staphylococci, streptococci and a few unclassified pneumococci. However, when inoculated into a mouse, a pure culture of Friedländer bacillus type A was recovered from the peritoneal cavity and the brain of the mouse. This was repeated June 20 and the Friedländer organisms and a few pneumococci type XI were recovered from the peritoneal cavity of the mouse. July 11, bronchoscopic examination revealed an inflamed bronchus in the right upper lobe with a large amount of non-foul mucopurulent sputum coming from this bronchus. This was not cultured. The bronchoscopic procedure was repeated August

(fig. 14). The patient was asymptomatic, and he was discharged to a convalescent home. He was seen again Jan. 20, 1940, and the roentgenogram, not reproduced here, showed no appreciable change.

CASE 4.¹⁶—J. M., a 41 year old white man, became ill six days before admission with an infection of the upper respiratory tract, followed by sharp pain in the right side of the chest and blood-streaked sputum. He was admitted Nov. 2, 1939, appearing acutely ill with a temperature of 104 F. The sputum was the characteristic mixture of mucus and blood. There was consolidation of the right upper lobe (fig. 15).

The patient was icteric; the liver was enlarged and ascites was present. Dr. William Asterid, who had observed this patient for some years previously, stated that the diagnosis of hepatic cirrhosis had been made in 1935 and that up to the time of the present illness there was no pulmonary disease.

The sputum on admission and several days later showed a pure growth of the Friedländer bacillus type B. The blood culture made on admission showed one colony of this bacillus. The cultures November 4 and 5 were sterile but on November 6 there was again a growth of the Friedländer bacillus type B in the broth despite the fact that he was receiving sulfapyridine.

Sulfapyridine therapy was begun on admission, 2 Gm. being given at once and 1 Gm. every four hours until November 13, when the dose was halved and continued for four more days. He received a total of 80 Gm. of the drug.

Fig. 11 (case 3).—June 23.

Fig. 12 (case 3).—July 7, abscess with a fluid level.

Fig. 13 (case 3).—August 31, clearing of the pneumonic zone. The abscess is large but empty.

4 with the aspiration of scanty thick sputum from the bronchus of the right upper lobe; on culture this yielded pure Friedländer bacillus type A. Bronchoscopy and culture of the material obtained were done one week later with the same result.

The clinical course was severe during the first two weeks. There were signs of consolidation of the right upper lobe and an x-ray film June 23 (fig. 11) showed a dense homogeneous shadow with a convex lower border as if there might be an encapsulated effusion. Exploratory thoracentesis yielded no fluid.

Sulfapyridine was employed, 1 Gm. being given every four hours for ten days, after which the temperature came down by lysis and the drug was discontinued. He received a total of 55 Gm. No toxic symptoms were noted.

The white cells on admission numbered 13,200 with a shift to the left. Within a few days the count rose to 22,750 with a greater shift to the left. Following this there was a gradual fall in the white cell count. The red cells and hemoglobin were moderately low on admission and did not rise till after the acute phase passed. The erythrocyte sedimentation rate (Westergren) averaged 40 mm. during the acute stage of the illness and gradually came down to normal.

Serial x-ray studies (figs. 12 and 13) showed abscess formation with fluid level although the sputum was never foul. There was gradual clearing of the pneumonic zone surrounding the abscess. Agglutinins against the Friedländer bacillus type A appeared in the blood. The cavity decreased in size progressively, and the roentgenogram made October 23 showed merely an area of infiltration in the second and third right interspaces which may represent either a residual cavity or bronchiectasis

The patient gradually improved and the temperature fell by lysis November 5, although he appeared toxic for some weeks after. The pneumonic area began to slough out and a definite lung abscess developed in the periphery of the second interspace (fig. 16). The character of the sputum changed, becoming copious and mucoid and containing mixed organisms as well as the Friedländer bacillus. Agglutinins against the Friedländer type B organism were present November 6 and persisted for several weeks. It is of interest that for a short time agglutinins were also present for the pneumococcus type II, whose capsule is closely related to that of the Friedländer type B organism.

The white cells on admission numbered 4,200 with a marked shift to the left, but within a few days the count rose to 23,000 and then leveled off at 14,000 with a normal differential count.

A complicating factor was the presence of cirrhosis of the liver with ascites. Abdominal paracentesis was done and 5 quarts of fluid removed. The small abdominal incision necessary for this procedure remained patent and drained for weeks. The edges of the wound appeared necrotic and devitalized, though not infected. It was assumed that this was a sulfapyridine effect on the tissues, since a similar phenomenon was observed in another patient (not in this series) who after a laparotomy contracted pneumonia and was treated with sulfapyridine. The operative wound appeared devitalized and dehiscence occurred with evisceration and a subsequent fatal outcome.

16. Dr. Asa Lincoln gave permission to present this case.

Later roentgenograms (fig. 17) show considerable clearing of the lesion and shrinkage of the lung abscess. It seems likely now that he is recovering from his pulmonary infection, although the associated portal decompensation appears serious.

CASE 5.—E. M., a 46 year old white woman, gave a history of several attacks of pneumonia during the past ten years. During one of these attacks of which there is record, in 1931 she had pneumonia of the left upper lobe which cleared up spontaneously. No sputum typing was done. She subsequently complained of chronic cough and was observed in the clinic of New York Hospital in 1934. The sputum was not examined, but a roentgenogram was taken which showed increased bronchial markings. Neither this picture nor the ones taken at Bellevue Hospital are shown here because of lack of space.

She was admitted to Bellevue Hospital Nov. 30, 1939; there had been an acute onset one month before with shaking chills, pleuritic pain and the production of thick yellow sputum.

She appeared acutely ill with a fever of 104 F., consolidation of the left upper lobe and empyema necessitatis in the left axilla. There was also swelling of the left arm with a tender cord in the axilla which was believed to be a thrombophlebitic axillary vein.

The roentgenogram showed consolidation of the left upper lobe and encapsulated empyema. Thoracentesis yielded 30 cc. of thick creamy pus which showed Friedländer bacilli type A

Fig. 14 (case 3).—October 23, shrinkage of the abscess and residual infiltration.

in pure culture. The sputum was also thick and creamy and showed a predominance of gram-negative rods in the direct smear. Sputum typing showed the Friedländer bacillus type A and pneumococcus type X. The white cells numbered 22,000 with 90 per cent polymorphonuclears. The blood culture was sterile.

Thoracotomy was done December 2 with resection of a piece of the second rib and drainage of the empyema as well as the lung abscess in the left upper lobe. A bronchopleural fistula was noted.

Sulfapyridine was started on admission, the same dosage being employed as in case 3. The temperature fell to 100 F. December 1, although low grade pyrexia persisted for some time thereafter. The thrombophlebitis subsided. The patient is still in the hospital at the time of writing. Although she has shown considerable clinical improvement, she still has a draining fistula and a residual abscess in the left upper lobe.

CASE 6.¹⁷—A. G., a white man aged 50, became ill Oct. 6, 1938, with weakness, vomiting, chills, pain in the right side of the chest and cough with scanty salmon-colored sputum.

The patient was acutely ill and dyspneic on admission October 10, and there were signs of pneumonia in the right upper lobe, which was confirmed by x-rays. The temperature was not high, ranging between 100 and 102 F. Sputum typing and sputum culture at first yielded a pure growth of Friedländer bacilli, although the type was not determined. Later in the course of the disease the Friedländer organism was found in the sputum only in association with streptococci, staphylococci and other organisms. The blood culture on admission showed one colony of Friedländer bacillus. Subsequent cultures were sterile.

Sulfanilamide was employed, 1.3 Gm. being given every four hours, and this was maintained for three weeks until a total of 163.8 Gm. had been administered.

Serial roentgenograms showed unresolved consolidation of the right upper lobe with several cavities. The temperature fell by lysis, reaching normal October 16, although there was little clearing of the pneumonic lung. The white cells numbered 7,400 on admission and gradually rose to 27,400 after two weeks, with a subsequent slow fall in the count.

The patient was discharged December 14, still showing infiltration and cavities in the right upper lobe. He is observed in the clinic at intervals and complains of cough and mucoid sputum. Culture of the sputum on agar pour plates Jan. 5, 1940, yielded Friedländer bacilli type A and numerous other organisms. A roentgenogram taken Nov. 25, 1939, still showed productive changes and cavities in the involved lobe.

SUMMARY

1. Seventeen cases were observed of chronic pneumonia due to the Friedländer bacillus, a clinical condition which is rather unique in a number of ways. Generally following on the heels of the acute disease, the chronic infection lasts for months or years if a fatal issue is avoided.

2. The causative organism was isolated in pure culture in every case during life from one or more of the following sources: sputum, pleural fluid, lung fluid and blood.

3. The disease is more common in males, it occurs mainly in the fifth and sixth decades of life, and the chronic form has never been observed in childhood.

4. The onset of the illness is usually acute, the disease after a few weeks assuming the features of chronicity. The temperature is irregular, febrile periods often alternating with periods of normal temperature. In this series, the disease lasted from one month to more than three years. The mortality was 23.5 per cent.

5. Bacteremia occurred in 31 per cent of these cases as compared with an incidence of 70 per cent in the acute Friedländer pneumonia. However, in both groups of cases, the degree of blood stream invasion is mild and does not play any apparent role in the cause of death.

6. The upper lobes were the most favored sites, being involved in 82 per cent of the cases. Multiple lobe involvement was present in 30 per cent of the cases.

7. The sputum is often characteristically mucoid and bloody in the early stages, later becoming mucopurulent if suppurative changes occur. A direct smear of the sputum frequently reveals typical large encapsulated gram-negative bacilli. Mouse inoculation early in the illness generally yields a pure culture of the Friedländer organism. The bacilli may be further classified by agglutination tests and the capsule-swelling method into groups A, B, C and D. Nine of our cases were so typed, revealing seven cases of type A, one of type B and one of type C.

During the later stages of the disease, the Friedländer organism is no longer present in pure culture but is found mixed with or overgrown by secondary invaders.

8. Complications were chiefly limited to the chest and included lung abscess, bronchiectasis, pulmonary fibrosis, pleural effusion and empyema. Of these, the most frequent were lung abscess, occurring in almost 60 per cent of the cases, and empyema, which occurred in 23.5 per cent of the cases. In three of the four fatal cases there was lung abscess or empyema or both.

9. Because of the frequent occurrence of blood streaking and mucopurulent sputum and the x-ray appearance of upper lobe cavities, the condition, if the patient is seen for the first time at this stage, is commonly mis-

17. Dr. James Liebman gave permission to present this case.

diagnosed as pulmonary tuberculosis. However, a careful evaluation of the history, clinical evidence and bacteriologic study of the sputum will reveal the true nature of the disease.

10. Sulfapyridine was employed with four patients, all of whom recovered though pulmonary suppuration continued with little apparent effect. One bacteremic patient was treated with sulfanilamide and recovered, though he too contracted lung abscesses.

This is the first report in the literature dealing with the use of sulfapyridine in this disease. Despite the fact that the number of cases reported here is not large the results are sufficiently encouraging to warrant further trial of sulfapyridine in Friedländer infections of the lungs.

LEAD ABSORPTION FROM BULLETS LODGED IN TISSUES

REPORT OF TWO CASES

WILLARD MACHLE, M.D.

CINCINNATI

Whether bullets remaining in tissues can give rise to lead poisoning has long been a subject of discussion. The great body of opinion, first expressed by Paré, holds that bullets in tissues will not cause intoxication, but there have also been proponents of the opposite point of view, and cases of plumbism from retained bullets have been reported from time to time, the earliest record being that of Bronvin¹ in 1867. Among the more than fifty publications on this subject there are reports of forty cases in which the clinical diagnosis of plumbism resulting from retained bullets has been made.²

From the Kettering Laboratory of Applied Physiology, University of Cincinnati.

The entire assumption of the occurrence of plumbism from retained bullets being dependent on the occurrence of clinically identifiable lead poisoning, it would seem desirable at the outset to state the criteria on which my associates and I base such a diagnosis. They are the existence of (1) significant lead absorption, as evidenced by the presence of abnormal amounts of lead in the body fluids or tissues, (2) clinical signs and symptoms consistent with lead intoxication and (3) other laboratory observations that will support the diagnosis.

Analytic evidence of significant lead absorption, while not a sine qua non for diagnosis, affects the likelihood of the existence of intoxication so markedly that in practically all instances quantitative data on the lead content of the urine and blood are most desirable. Unfortunately, when most of the cases were recorded precise analytic methods were not available and the data on which the diagnosis of plumbism was based were not quite complete. Furthermore, as a consequence of the development of adequate procedures for lead analysis refinements in the diagnosis of plumbism have been made, and the significance of clinical symptoms and signs is now subject to somewhat more critical interpretation. For example, the presence of a lead line and the occurrence of stippling in the erythrocytes may now properly be regarded as evidences of lead absorption alone, with no certainty that intoxication exists.

Fig. 1.—Lead excretion in case 1.

Obviously many persons have carried bullets about in their bodies for decades without acquiring plumbism. Lead bullets are not in all cases inert, however. In our cases³ determination of concentrations of lead in the urine and blood demonstrated that lead absorption of a magnitude comparable to that encountered in lead trades can result from embedded bullets. Furthermore, in one case with removal of the bullet and excision of contaminated tissues the abnormal absorption stopped and the concentrations of lead in the urine were reduced:

CASE 1.—L. C., a man aged 27 first seen in the orthopedic service at the Cincinnati General Hospital, had carried a pistol bullet in the head of the right femur for some six or seven years. In the interval the patient had not been well. Local

3. These cases were referred to us by Dr. Joseph A. Freilich, director of the orthopedic service of the Cincinnati General Hospital, who performed the operation in case 1.

symptoms were severe, and dizziness, headache and malaise had become increasingly noticeable during the past year. At the time we examined him the clinical picture did not seem sufficiently characteristic to justify a diagnosis of incipient plumbism, especially in view of co-existing marked gingival and tonsillar infection.

Samples collected on the day prior to operation contained 0.20 mg. of lead per liter of urine and 0.09 of lead per hundred

Fig. 2 (case 1).—Appearance in 1934, soon after the wound had been sustained.

grams of blood. These levels are significantly elevated and are comparable to those encountered in subjects with severe industrial exposure associated with intoxication. The bullet and contaminated tissues were removed and a vitallium cap was inserted. Subsequent samples, as shown in figure 1, revealed a steady decrease in the lead concentration in the blood

Fig. 3 (case 1).—Appearance in 1939, prior to operation.

and variable lower levels in the urine, both tending downward though not reaching normal ranges in the ten weeks following operation. In view of this reduction in the lead concentrations after removal of the bullet and the absence of any known lead exposure prior to operation, we attributed the lead absorption to the bullet. Three roentgenograms (figs. 2, 3 and 4) taken shortly after the injury, just before operation and following operation demonstrate the solution and local dissemination of

substance from the bullet, the degree to which the joint capsule and adjacent tissue were infiltrated with lead⁴ and finally the extent of removal.

CASE 2.—C. B. was wounded by a pistol bullet in the right wrist. The embedded bullet caused deformity and impaired function but there were no general symptoms indicating lead intoxication. Roentgenograms taken shortly after the wound was sustained (fig. 5) showed the clearly defined foreign body with but little shattering of the deformed projectile. The second film (fig. 6) made seven weeks later already showed some evidence of beginning solution. In the last roentgenogram (fig. 7), five years later, evidences of solution and local deposition of lead were distinct. The concentrations 0.07 mg. per hundred grams in the blood and 0.07 mg. per liter in the urine were definitely higher than those of normal persons. Since an operation has not yet been performed I cannot report on the behavior of the lead concentrations following removal of the apparent source of absorption.

The analytic and x-ray studies in these two cases leave little doubt that under certain circumstances lead in retained bullets is acted on by the tissues and made available for absorption into the general metabolism. This observation has been made earlier. Two cases of

Fig. 4 (case 1).—Appearance after operation.

Wieting and Ibrahim⁵ showed x-ray evidence of local dissemination more extensive than that seen in our cases, despite which there were no clinical symptoms or evidences of lead absorption. In the case of lead intoxication reported by Haenisch,⁶ roentgenograms with an interval of twenty-two years demonstrated a similar behavior. Furthermore, in at least fifteen of the reported cases of plumbism from bullets there was evidence of local dissemination in the bluish gray discoloration of adjacent tissues similar to that seen in our case. The presence of crystalline deposits of what seemed to be metallic particles in adjacent tissues led some observers to conclude that the local dissemination and discoloration had resulted from comminution of the projectile. Study of roentgenograms from our cases and others in which serial pictures were taken indicates that, even though fragmentation is of importance in that it increases the surface available for solution, it is not alone responsible for the local changes.

It is known that lead compounds are soluble in the tissues and body fluids; moreover it has been shown

4. A portion of the joint capsule on analysis was found to contain more than 3 per cent of lead.

that the solubility of metallic lead is greater in fats and biologic fluids than in water, particularly in the presence of higher tensions of carbon dioxide.⁷ This indicates how metallic lead in the tissues may serve as a source of lead absorption; it does not, however, elucidate the mechanism of the local redeposition. This may result from chemical differences between healing wounds and adjacent uninjured tissues. That mechanical factors such as abrasion may accelerate solution of the projectile is illustrated in the case of Kohlschütter,⁸ in which the shrapnel bullet was embedded in the lateral fossa of the articular surface of the tibia exposed to joint action. In five years there was considerable loss of material from the bullet and extensive deposits about the knee joint, the popliteal bursa being filled with a frothy grumous gray mass and the joint capsule and cartilage colored a bright blue. In our first case the bullet was exposed on the head of the femur and showed wear from action of the joint.

A study of the reported cases was undertaken in an attempt to estimate the importance of any other factors

which might influence absorption. Details of the cases are given in table 1 and a summary of the significant observations in table 2.

As far as I have been able to determine, these forty cases comprise all the published cases of lead poisoning from bullets lodged in tissues. One is impressed first of all with the paucity of cases as compared to the frequency both of gunshot wounds and of bullets that have been permitted to remain in the body. I took as my criterion for inclusion in this study the fact that a clinical diagnosis of lead intoxication had been made by the respective author, without regard to the probable validity of the diagnosis. Exceptions are the six cases reported by Lewin in 1892, when Küster and Lewin⁹ first interested themselves in this problem. These had been reported by other authors; Lewin averred that lead intoxication had been responsible for the symptoms in each case but had been overlooked.

It is apparent that plumbism was not associated with any particular type of missile. Under the heading

* Bathed with synovial fluids. † Other diseases not specified.

"bullet" I have included rifle and pistol bullets as well as musket balls. Shot—"bird" and "buck"—accounted for a fairly high proportion of the cases, and this is particularly noteworthy when one considers the large number of shrapnel and rifle bullet wounds sustained in the war of 1914-1918. Evidence from *in vitro*

Fig. 5 (case 2).—Appearance in 1934, shortly after the wound had been sustained.

experiments¹⁰ has indicated that solution of lead from jacketed bullets occurs and may exceed in degree that from uncovered lead, but there is no clinical evidence to bear this out.

The interval between lodgment of the bullet and onset of symptoms diagnosed as due to plumbism was widely variable (from twelve days to forty-eight years). Of the thirteen cases in which the symptoms developed in less than one year, only two would be considered cases of plumbism at the present time. In the one case¹¹ the onset occurred two months after the wound was received. The bullet was in the head of the tibia, however, was exposed on the articular surface and was found to be greatly worn by action of the knee joint. In the second case,¹² in which intoxication followed three months after shot wounds of the bones of the shoulder and foot were sustained, local dissemination of the shot was noted.

More than half the missiles were in the bones or joints, and in eight of these cases it was specifically stated by the author that the missile was bathed with synovial fluid. In all but two of the ten cases of probable intoxication the bullets were lodged in bones or joints.

Dissemination, which was noted in fifteen cases, was in some instances associated with shattering of the projectile; in others it was due solely to solution and redeposition of the lead.

More than half the patients had some associated disease at times related to the wound. In nine cases suppuration and fistulas were present at the site of the wound and evidences of arthritis were noted when the wounds were near joints (five cases). Other

diseases were gas bacillus infection, coronary thrombosis, diabetes, duodenal ulcer in two, neurasthenia, and post-traumatic epilepsy. In instances in which laboratory evidence of significant lead absorption is wanting, it is often impossible to be entirely certain that the symptoms were due to plumbism, particularly when the clinical manifestations on which the diagnosis of plumbism was made were those frequently resulting from the associated disease. For example, in one report¹³ the patient was said to have intermittent claudication, arteriosclerosis, chronic nephritis, diabetes and coronary infarction and while under study was operated on for gangrene of the foot. This patient had had a 2.5 Gm. bullet in his brain for forty-eight years. No characteristic symptoms of lead intoxication were present, the diagnosis being based on the presence of lead in the tissues obtained at necropsy. These amounts, particularly in the brain, were somewhat larger than those normally encountered in this country, but their presence without clinical symptoms of plumbism merely indicates that the lead absorption of the patient has been greater than normal.

Vomiting, constipation or colic were present in twenty-seven cases. Three patients had all three symptoms, eight had constipation and colic alone. In seven colic was the only symptom of the digestive tract noted.

Neuromuscular symptoms or symptoms of the central nervous system were frequently present; six patients had antibrachial paralysis, and in one case there was an associated hemiplegia. Delirium and convulsions were present in two cases and were attributed to lead encephalopathy. One of these patients had epilepsy; however, while in the other case the only signs of lead

Fig. 6 (case 2).—Appearance seven weeks later than the view shown in figure 5.

intoxication were lead line and digestive symptoms. Stupor or amentia was present in three cases and neurasthenic or psychasthenic symptoms were present in three. In four cases arthralgia, tremor and paresthesia were the only disturbances noted.

The lead line, present in sixteen cases, may be taken as evidence of lead absorption, and the same is true

for stippling, present in fifteen cases. Both stippling and anemia were of lower incidence than would be anticipated in cases of frank plumbism such as are seen in industry.

Of particular interest would have been the progress following removal of the bullet, which was done in most cases. Unfortunately, in more than half the cases death occurred or notes on the postoperative course were omitted.

Fig. 7 (case 2).—Appearance in 1939.

COMMENT

Not more than eight or ten of these cases at most will certainly satisfy present day requirements for the diagnosis of lead poisoning. In most instances the symptoms would be attributed to other causes. With the present means for determining the magnitude of lead absorption, uncertainty need no longer exist. If significant amounts of lead are being absorbed from a projectile in the tissues, the fact may be established readily and the likelihood of intoxication estimated.

The question of the advisability of removing bullets wherever possible has been raised by many authors. Bronvin,¹ Lewin¹⁴ and others held that intoxication from bullets occurred with greater frequency than was suspected, while others, as Bonhoff,¹⁵ Hofbauer,¹⁶ Dennig¹⁷ and Neu¹⁸ and clinical surgeons have denied this emphatically. A few, particularly Braatz¹⁹

and Habs,²⁰ are of the opinion that plumbism from bullets may occur rarely but that this does not constitute an adequate indication for removal of the projectile in all cases. Much of the confusion is due to differences in the interpretation of analytic results and, to a greater extent, to differences in opinion as to what constitutes the clinical entity known as plumbism. For example, Neisser,²¹ Lewin, Schlesinger²² and others considered a positive qualitative test for lead in the urine, blood or spinal fluid as evidence of intoxication, while Hofbauer, Dennig, Neu and Lipp²³ considered such a finding devoid of diagnostic significance in the absence of clinical symptoms of intoxication. The accepted view at present is that, since lead is normally present in small amounts in the body fluids, quantitative data are necessary and results are significant only when normal levels are exceeded.

Opinions on the clinical diagnostic criteria are as diverse as those regarding the laboratory data. One extreme of opinion expressed by Haenisch⁶ is that instances of "fatal plumbism can occur in which the known usual signs of the disease are lacking," and Neisser considered the presence of neurasthenic symptoms to be adequate evidence of lead intoxication. On the other hand, after critical examination of cases reported up to 1922 Bonhoff¹⁵ concluded that the symptoms were in the main general and could be attributed to suppuration or other disease; in any event the cases had been too poorly studied to exclude other avenues of lead absorption or the effects of improvement in the diet and regimen in the hospital. Habs²⁰ studied the thirty-six cases reported up to 1927 and considered six as cases of proved plumbism, the remainder doubtful.

My opinion from a study of the forty cases reported up to this time conforms with that of Habs. I have found eight or ten cases of probable lead intoxication. Of these only three²⁴ satisfy all the criteria in that quantitative analytic data were obtained on body fluids; in seven other cases²⁵ the clinical evidence makes the diagnosis seem probable.

CONCLUSIONS

There are forty reported cases of lead poisoning from bullets lodged in the tissues. Only three fulfil all modern criteria and in seven others the diagnosis seems probable. A further thirteen showed signs of lead absorption.

Poisoning from this source is a rarity, but lead absorption can occur from bullets lodged in the tissues, particularly in bones at the joints, as in the two cases reported in this paper. The possibility of delayed intoxication should have some weight in the decision as to the removal of bullets.

THE NEWBORN NURSERY FROM THE POINT OF VIEW OF THE PEDIATRICIAN

JULIUS H. HESS, M.D.
CHICAGO

I have selected this subject for joint discussion in this obstetric-pediatric symposium because it offers controversial material for our consideration which carries with it responsibilities of interest to the obstetrician, the pediatrician and the man in general practice. A discussion such as this would not be inclusive unless one considers the newborn nursery as found in the large general hospital with both open and closed staffs, the special lying-in hospital, and the local hospitals widely scattered in the smaller cities throughout the various states.

Only a few of our larger cities can support a special maternity hospital and therefore it becomes necessary for the general hospital to establish special departments for obstetric cases which must provide the best care possible for the mothers and their babies. Many of our hospitals were built in the past, when hospital deliveries represented 25 or 30 per cent of a community's total deliveries, and were not equipped to meet the exigencies of the present day, when as many as 85 per cent of deliveries occur in hospitals. In Chicago during 1939, of 48,909 live births 84.8 per cent of all deliveries took place in sixty-nine hospitals; 14.1 per cent in homes were delivered by doctors, and approximately 1 per cent by midwives. In 1939, 4,670 live babies were born in Cook County Hospital.

In many instances the modernizing of delivery rooms has preceded the improvement of the newborn nursery.

In full appreciation of the fact that a high percentage of all deliveries in the United States are conducted by physicians in general practice, responsibility for the lowering of infant mortality and morbidity nevertheless rests to a large extent on the provisions for the safe care of the mother and child which in their wisdom have been adopted through mutual agreement by departments of health and the medical members of hospital staffs more directly interested in obstetrics and the newborn infant.

The reduction of maternal and infant death rates throughout the United States, and we cannot separate consideration of results attained for both the mother and the child, in the past ten years stands out as a striking answer and refutation of the popular uncensored articles appearing in the lay journals. In Illinois, the state with whose activities dealing with maternal and child welfare I am best acquainted, as an example, there has been a reduction in maternal deaths from 5.23 per thousand births in 1930 to 4.55 in 1935 and 2.88 in 1939, and in Chicago from 4.95 per thousand births in 1930 to 3.46 in 1935 and 2.5 in 1939. These figures speak for themselves.

Even more striking has been the lowering of infant mortality in Illinois in the first month and first year of life, from 56 per thousand live births in the first year of life in 1930 to 45.9 in 1935 and 37.88 in 1939, and in Chicago from 53.4 per thousand live births in 1930 to 40.1 in 1935, 33.7 in 1938 and 31.3 in 1939, or a drop of 41.38 per cent in the last ten years. These figures are representative of what is being noted

throughout the United States. We are all agreed that they do not represent the ultimate results to be attained, but they speak well nevertheless for the constructive efforts of those who have been most instrumental in making this possible.

As far as the infant is concerned, the least progress has been made in the number of deaths within the first day, the first week and the first month of life. Many of our states and cities are now concentrating more definitely on the care of the newborn infant in its first days, and especially on the care of the prematurely born infant. It is unfortunate that, in the quoting of statistics, more definite stress has not been placed on the different races of our population, with special consideration of the urban and rural facilities available.

The accomplishment of the best attainable results will be dependent on definite vesting of authority for the conduct of the maternity division and the newborn nursery in reliable and deeply interested medical staff members under whose authority and direction the nursing staff functions. For the safeguarding of the best interests of the mother, her child, the hospital and the prestige of the medical profession, a willing and able consulting staff must also be available.

In the institutions with which I have been connected, confusion and the working at cross purposes have largely been dependent on the absence of regular and constructive conferences between the obstetricians responsible for the maternity wards and the pediatricians or the practitioners in whose care one may find the infants.

Among the provisions of exceptional importance to the newborn are (1) the establishment of regulations covering the conduct of the puerperium as related more especially to the care of the mother's breasts, (2) who shall assume the responsibility of establishing and promoting breast feeding in the early days of the puerperium, and (3) the placing of definite responsibility for the general conduct of the nursery.

At a recent meeting of the American Academy of Pediatrics, one of the discussers remarked that in his community the breast-fed infant was a rarity—this in contradistinction to the results achieved in our Cook County Hospital, where approximately 85 per cent of the mothers are discharged with their babies feeding at the breast.

Few who have had experience in the management of infants will deny the importance of breast feeding, but many who acknowledge its importance do little to encourage it. I am certain we all agreed that many more children should be breast fed than are at the present time. There are many possible causes of failure on the part of the mother to meet her infant's needs, but faulty management is undoubtedly the most common.

It has been my experience that the obstetrician often gives excellent general care to the mother during the latter months of her pregnancy but pays little or no attention to her breasts, especially in the matter of preparing the nipples for the trauma of lactation. Many obstetricians believe that excessive antepartum manipulation of the nipple is of only moderate benefit, and I think that we will all agree that in the nipple with congenitally short ducts the result is usually disappointing. I do not overlook the fact that some breasts are not fitted by nature to function adequately, because of insufficient glandular element.

The first days are the danger period to successful breast feeding. First, the obstetrician provides for the mother his most solicitous attention; he has practiced his best obstetrics and has presented her with a normal, uninjured infant. His fears, if any, are centered on the possibility of postpartum complications in the mother. Not the least of these is his desire to avoid trauma to the nipples, with their further danger of secondary breast infection.

As the obstetrician is responsible for the relief of the original hyperemia, guarding against cracked or bleeding nipples and their general care, instruction for their care will naturally be assumed by him. If the mother develops mastitis and breast surgery becomes necessary, the responsibility for such a condition is his. Consequently, I believe that the establishment and maintenance of breast nursing in the early days should be assumed primarily by the obstetrician. If the obstetrician is seriously interested in breast feeding, I believe there should be no conflict of opinion.

I wish, however, to emphasize that if the pediatric representatives do not have access to the mother's breasts so that they can judge their ability to respond to the baby's efforts or those of manual expression, the responsibility of the pediatric service to the newborn is not fulfilled.

What then are the pediatrician's responsibilities? I believe that, where he has been made responsible for the nursery care of the newborn, the conduct of the nursery in its entirety should be his responsibility. The supervising nurse of the nursery should be responsible to the pediatrician and should in turn be under the jurisdiction of the chief nurse in the obstetric department, the latter acting as a liaison officer between the obstetrician and the pediatrician. The nurse in charge of the nursery therefore should be pediatric minded and should of course have had obstetric experience.

It is unfortunate that in some of our institutions, notwithstanding the fact that a visiting pediatrician is responsible in name, he does not assume his full duties. I take it for granted that it is understood that I have been talking largely of service cases. It must of course be realized that, as far as private cases are concerned, the dividing of responsibility for the care of the infant is one of mutual consent.

Most of the responsibility for the service must be left in the hands of the obstetric resident or senior intern, if there is no resident. Joint daily rounds should be made in the nursery by the obstetric and pediatric residents. Causes for weight loss are to be sought for in both mother and infant. On the part of the mother delayed secretion, sore or fissured nipples, depressed nipples, congestion of the breasts and actual insufficiency of secretion due to quality of the breasts must all receive consideration. As far as the infant is concerned, all factors which might be causes for poor nursing must be sought for, more especially congenital anomalies, immaturity and birth hemorrhage.

At stated intervals, rounds of the lying-in division and nursery should be made by the obstetricians and pediatricians so that there can be a definite understanding covering the views of both departments concerning the care of the mother's breasts and the technic established in the nursery.

The chief obstetric nurse, the nurse in charge of the newborn nursery and the house staff should be included in these ward rounds. Much misunderstanding can also be avoided in institutions where the man

in general practice does his own obstetric work and assumes the responsibility for the care of the infant, through such conferences. It must be remembered that the bulk of deliveries throughout the country are under the care of men in general practice.

FEEDING REGULATIONS

Now let us look back a century and a half and note the fine wisdom of William Cadogan (1711-1797). In "An Essay upon Nursing and Management of Children from Birth to Three Years," published in 1748, he states:

I am confident from experience that with a Child kept without food of any kind until it was hungry, which it is impossible it should be just after birth, and then applied to the Mother's breasts, it would suck with strength enough, after a few repeated trials, to make the milk flow gradually in due proportion to the Child's unexercised faculty of swallowing and the call of its stomach.

Four times in four-and-twenty hours will be often enough to give it suck; letting it have as much as it will take out of both breasts at each time. The Mother's milk seldom comes until the third day. The Child is born full of blood, its appetites not awake, nor its senses opened; and requires some intermediate time of abstinence and rest to compose and recover from the struggle of the birth and the change of circulation.

Dry-nursing (artificial feeding) I look upon to be the most unnatural and dangerous method of all. To breed a Child in this artificial manner requires more knowledge of Nature and the animal economy than the best Nurse was ever mistress of; the skill of a good Physician would be necessary to manage it rightly.

At the Michael Reese Hospital the following is the routine practice: Normal full-term infants are placed at the breast six hours after delivery, and then for not more than five minutes on either breast, and thereafter at four hour intervals five times during the twenty-four hours. Water without carbohydrate addition is fed to the infant six times in twenty-four hours, in amounts of 1 ounce at first and up to 2 or 3 ounces later. Infants are kept under close observation for evidence of inanition. If at the end of the fourth day the breasts are still not showing evidence of secreting an adequate amount of milk, a milk mixture is started as a complement. Usually both breasts are offered at a nursing. In our experience the average infant leaving the hospital at the tenth day after birth has reached a weight within 100 to 150 Gm. or less of its birth weight.

Since most cracked nipples develop during the first four days, this is the important period for prophylaxis. Factors which should be recognized as helpful aids to breast feeding are:

The application of the breast pump or hand expression for aid in developing the retracted nipple.

The placing of the infant at the breast for not more than five minute periods during the first three or four days, or preferably at both breasts for even shorter periods.

Simple depression of the lower jaw of the infant should be practiced at the conclusion of feeding to prevent trauma as the infant is being removed from the breast.

In the presence of cracked nipples the infant may well be taken off the breast temporarily, and hand expression or breast pump should be used during that time to promote secretion.

At Cook County Hospital, twenty-four hours after birth the infant is fed an ounce or 1½ ounces of breast milk obtained from wetnurses, the objective

being to implant *Bacillus bifidus* in the intestinal tract. This organism keeps the p_H very low, thereby retarding the growth of the colon group of organisms. The infant is not placed to the breast until after this first feeding of breast milk. With this procedure the early stools of the infant are of the so-called breast-fed type. There have been no severe diarrheas in this newborn nursery in the last three years.

ADVANTAGES OF JOINT OBSTETRIC AND PEDIATRIC ARRANGEMENT

The advantages of a joint obstetric and pediatric arrangement are:

1. The physician in charge of the mother will have evaluated her possibilities for breast feeding and by advice often avoid the anxiety of the mother as to her ability to carry on when at home, when she so often learns for the first time that her crying baby is simply carrying on the same performances that he was accustomed to in the hospital nursery.

2. On discharge from the hospital there will be avoided abrupt changes in routine in the care of the infant, as is so often the case when the pediatrician does not enter the picture until the infant is returned to its home.

Every mother should be taught manual expression while still in the hospital. The nursing division has not performed its obligation to the mother and infant unless the mother has been taught manual expression, if for no other purpose than that breast bottle feeding can be provided in case of emergency. The electric pump has a large and successful place in the hospital nursery; however, it carries the danger that hand expression may not be taught the individual mother. The infant is, of course, by all odds the best breast pump.

PREPARATION FOR DISCHARGE

By the tenth or twelfth day the average mother is discharged from the hospital and assumes the responsibility for the care of her infant in the home. With what preparation does the average mother in moderate circumstances who cannot afford a trained nurse or nurse maid assume her home care of the infant?

The individual instruction in some well organized hospitals is good; in most of them it is indifferent. She may be given some printed directions or a board of health God's blessing and the good wishes of the obstetric department. When, in at the most four hours from the time she has left the institution, the infant starts the well rehearsed performance which he has so well practiced and which has achieved the desired results but with which the mother was so little acquainted, there starts the chain of circumstances which I am sure I do not have to recount for your information, for they are only too well known to you, your own household and the telephone company, the results being a decrease in or even a drying up of the breast milk supply.

CONCLUSION

I would urge that staff conferences open to all local physicians should be held at stated times in all hospitals. At such meetings all phases of maternity and newborn care should be discussed, and their value becomes increasingly productive when individual records and cases are discussed.

It has been the experience of those interested in furnishing so-called refresher courses in obstetrics and pediatrics that the progressive physicians are in regular attendance, while those who might profit most are

conspicuous by their absence. Sooner or later all must avail themselves of hospital service for their patients, and it is in the community hospital that they can best be contacted.

In every city or town "Every hospital should be a teaching center."

104 South Michigan Avenue.

Clinical Notes, Suggestions and New Instruments

NERVE ROOT INFILTRATION IN MYELOGENOUS LEUKEMIA

J. P. MURPHY, M.D., AND B. S. BRODY, M.D.
NEW HAVEN, CONN.

Involvement of the central nervous system in the course of acute or chronic myelogenous leukemia is not unknown. As emphasized by Critchley and Greenfield¹ in their discussion of cord symptoms in leukemia and chloroma, the pathologic manifestations in such cases may be of several kinds. Localized collections or "tumor formations" of the abnormal white blood cells in the meninges are most common, according to these authors. The cases reported in their article of four males aged 19 years or younger were featured by the presence of such leukemic or chloroma masses in the epidural or subarachnoid spaces. In addition, however, a special finding in three of the cases was invasion of the spinal and cranial nerve roots by the myeloid elements, which in these cases apparently accounted, at least in part, for the radicular pains and other disturbances (including peripheral facial and palatal palsies, as well as unilateral deafness) from which the patients suffered. Root infiltration was also prominent in the report of Cornil and his associates,² but in that instance there were also an epidural tumor, hemorrhages and leukemic invasions in the parenchyma.

In the case which forms the subject of the presentation which follows, it is felt that the symptoms and physical manifestations are most readily explicable on the single basis of injury to cranial and spinal nerves secondary to the entrance of myeloblasts and myelocytes into the nerve roots.

Examples in the literature of other cerebrospinal complications referable to the blood dyscrasias, such as myelomalacia subsequent to thrombosis or compression or widespread extensions of the abnormal cells into gray and white matter,³ will not be referred to in detail, since they are not pertinent to the present discussion.

CLINICAL HISTORY

P. M., a white man aged 39, a janitor, admitted to the Grace Hospital, Jan. 22, 1940, complained of inability to walk for the previous two and one-half weeks.

The onset of the present illness apparently occurred about four or five months before hospitalization. At that time vision in the left eye became blurred; the extraction of several teeth did not improve this difficulty. One month later the sight in the right eye began to fail and the patient rapidly became blind on that side, visual acuity in the left eye recovering meanwhile. He also noted that the right side of his face was somewhat asymmetrical. During an admission to another hospital both tonsils were removed, and severe bleeding persisted from the tonsillar beds postoperatively. The patient then realized that his legs were becoming weak; he felt tired and listless and noticed loss of weight.

Dr. C. J. Bartlett gave the authors permission to use the gross autopsy report.

3. Bassoe, Peter: Leukemic Infiltration in the Spinal Canal as a Cause of Paraplegia, *J. Nerv. & Ment. Dis.* 47: 180 (March) 1918. Reese, H. H., and Middleton, W. S.: Mechanical Compression of the Spinal Cord by Tumorous Leukemic Infiltration, *J. A. M. A.* 98: 212 (Jan. 16) 1932. Nordenson, N. G.: Nervous Complications of Acute Leukemia, *Sang* 12: 605 (No. 6) 1938.

For the two and one-half weeks before coming to the Grace Hospital, loss of strength in the lower extremities had been so extreme that he had been confined to bed. The right arm by this time was not as strong as formerly, there was partial deafness in both ears and the right facial weakness had become more marked.

The past and family histories were noncontributory.

On admission the temperature was 103 F. (rectal), the pulse 110 beats per minute, the respiratory rate 30 per minute and the blood pressure, 146 mm. of mercury systolic and 100 diastolic. The patient was well developed and appeared well nourished but chronically ill. Both ear drums were gray. The heart was not enlarged, there were no cardiac murmurs and the lungs were not unusual on percussion and auscultation. The edge of the liver was palpable two or three fingerbreadths below the right costal margin. A few slightly enlarged lymph nodes could be felt in each inguinal region. There was marked tenderness to percussion in the right costovertebral angle.

Fig. 1.—Myeloblasts and myelocytes in the cerebral meninges. Arrow indicates young myeloid cell with hyperchromatic nucleus. Giemsa stain; $\times 250$.

The patient was well oriented and the sensorium seemed to be intact. The sense of smell was present bilaterally. He was completely blind in the right eye, the fundus of which was obscured by haziness of the media. The nasal margin of the left optic disk was blurred and the retinal vessels were sclerosed. The right pupil was fixed to light, while the left responded sluggishly. There was no apparent defect in the left visual field. Slight nystagmus was present on right lateral gaze. The corneal reflex on the right was absent but that on the left was not. There was obvious right facial paralysis of the peripheral type. The right ear was completely deaf, and hearing in the left was impaired. The gag reflex was absent.

Both arms were weak, but not more so than could be accounted for on the basis of the patient's general condition. Biceps and triceps reflexes were in order. The abdominal cutaneous reflexes were absent on the right and sluggish on the left. Cremasteric responses could not be obtained on either side. There was a flaccid paraplegia of the lower extremities, and tendon jerks could not be elicited in the legs. The Babinski sign was absent bilaterally.

Vibratory sensation was impaired in each lower limb.

During the next two days the stools were noted to be tar colored, and tests revealed that they contained blood. Abdominal distention had appeared as well. A lumbar puncture, performed on the third hospital day, disclosed an initial pressure of 260 mm. of water, which fell to 160 mm. when 10 cc. of slightly

Fig. 2.—Section through lumbar spinal cord. Note heavy infiltration of roots of cauda equina. Nissl stain; reduced from a photomicrograph with a magnification of 10 diameters.

turbid fluid was removed. Examination of the specimen revealed the presence of 1,015 large mononuclear cells, 5 erythrocytes and 5 polymorphonuclear leukocytes in a cubic millimeter of the fluid. The results of a blood count on admission were (per cubic millimeter) red blood cells 4,100,000, hemoglobin 65 per cent (Tallqvist), white blood cells 12,000, differential count: polymorphonuclear leukocytes (segmented forms) 52 per cent, nonsegmented neutrophils 6 per cent, large lymphocytes 18 per cent, small lymphocytes 21 per cent, monocytes 0, eosinophils 3 per cent and basophils 0.

The spleen became palpable on the fourth hospital day and the liver seemed enlarged, as compared with the previous examination. Ascites was also detected. A papulopustular rash on the upper arms and trunk appeared the next day (fifth), the eyelids had become edematous and the right conjunctival sac was injected. The initial spinal fluid pressure on that day was 220 mm. of water; a web formed immediately on the surface of the fluid withdrawn and microscopic study of the specimen

Fig. 3.—Longitudinal section of the left acoustic nerve. Leukemic cells clumped between and among adjacent myelinated axis cylinders. Nissl stain; reduced from a photomicrograph with a magnification of 125 diameters.

revealed numerous small lymphocytes, many large mononuclears and several multinucleated giant cells.

The opinion of one of us (B. S. B.) at this time was that the patient was suffering either from a chronic infectious process of the central nervous system (such as tuberculosis or torulosis) or from myelogenous leukemia with cerebrospinal involvement.

A third spinal fluid examination was then made (sixth hospital day). The pressure was still elevated (230 mm. of water), and 2,560 large mononuclear cells, 3 small mononuclears and 70 erythrocytes as well as a few multinucleated giant cells were found in a cubic millimeter of the turbid fluid.

One week after admission an icteric tint to the skin and scleras was noted. The patient was incontinent of urine. Three days later the neck was slightly stiff, and the next day (tenth hospital day) he died. The temperature, which had fallen to around 101 F. shortly after admission, rose to 103 F. (rectal) just before death.

SUMMARY OF LABORATORY OBSERVATIONS

The red blood cell count ranged around 4 million per cubic millimeter with the hemoglobin content near 65 per cent (Tallqvist) during most of the patient's stay. The number of white blood cells varied from 12,000 to 14,000 per cubic millimeter. Numerous differential counts revealed from 40 to 60 per cent segmented polymorphonuclear leukocytes, from 10 to 20 per cent unsegmented neutrophils, from 9 to 18 per cent "large lymphocytes" and from 15 to 20 per cent "small lymphocytes." A few normoblasts were seen in smears of the blood taken in the last three days.

A positive test for albumin (1 plus) was recorded in all urinalysis reports. Rare white and red blood cells were seen in the urinary sediment on all occasions, with an occasional cast being discovered shortly before death. Specimens taken on the third and ninth hospital days were positive for bile.

The blood and spinal fluid Wassermann and Kahn reactions were negative.

NECROPSY

Postmortem examination was performed four hours after death. Petechial hemorrhages were noted in the skin of the body around the umbilicus. Six hundred cc. of clear yellow fluid was present in the abdomen. The liver edge extended 6 cm. below the right costal margin. Two hundred cc. of light yellow transudate was found in the right pleural space and 125 cc. of the same kind of fluid in the left pleural space. The lower lobes of both lungs were congested and edematous. The liver (2,890 Gm.) and the spleen (860 Gm.) were enlarged, and mottled areas were visible beneath the capsule and on the cut surface of the latter. The kidneys were pale. Several retroperitoneal lymph nodes were firm and large. Grayish red marrow filled the trabeculae of the ribs.

The cerebral meninges were thin and fairly translucent. A cerebellar pressure cone of moderate size was present around the medulla. What appeared to be petechiae were numerous on the cut surface of the white matter of both frontal lobes. The spinal meninges were slightly thickened and opaque, having a milky color. The parenchymal vasculature was unusually prominent. There were no other grossly visible changes in the cord.

Microscopically, large bizarre cellular elements were found in the leptomeningeal meshes and in the Virchow-Robin spaces surrounding the vessels of the gray and white matter in the brain and cord (fig. 1). In Nissl, hematoxylin-eosin and Giemsa preparations (particularly well demonstrated in the last) the nuclei of these cells were found to be big, vesicular and light or dark blue, and not infrequently in mitosis. The cytosomes were scant and faintly tinted (light pink); granules were seen in some cytosomes but were absent in most. These elements were myeloblasts and "early" (types A and B) myelocytes, the youngest cells predominating.

Most striking in the sections of the spinal cord and medulla examined was the extensive invasion of the nerve roots (figs. 2 and 3). Not only had the myeloid cells entered the fasciculi of the cranial and spinal nerves but there was also an accompanying Schwann cell proliferation, indicating a reparative process consequent on demyelination. Microglia and astrocytes were increased in number in the posterior horns of the cord, and exquisite "axonal" cell change (swelling of neuron, "ground glass" appearance of cytoplasm and nuclear excetration) featured the motor cells of the anterior horns. The ganglion cells of Clark's columns were reduced in number.

In a very few places the malignant cells had penetrated the molecular layer of the cerebral cortex and the most superficial

part of the cord, but not to considerable distances. "Marginal gliosis" had taken place in the gray matter immediately underlying the meninges, where the usually sparse meningeal infiltration was heavy. This too was only minor in degree.

"Chronic" cell change characterized a few neurons of the vestibular nuclei of one eighth cranial nerve.

The same myeloblasts were found in the sinuses of the lymph nodes and, as leukemic infiltrations, invaded the spleen, the liver, the adrenal, the pancreas and the pulmonary alveoli. Many such cells, with big nuclei sometimes containing nucleoli and occasionally with a few granules in their cytoplasm, practically constituted the myeloid portion of the marrow, the amount of erythropoietic tissue of which was in abeyance.

COMMENT

In the absence of extensive intramedullary cellular invasion, hemorrhages or infarcts, or compression of the cord by meningeal tumor formation, it is believed that the paraplegia which was so striking in the clinical picture of this patient resulted because of damage to the anterior and posterior roots of the spinal nerves. This is confirmed microscopically by the "axonal" type of cell change (similar to what is seen with section of the motor nerves) in the ganglion cells of the anterior horns of the spinal cord and by the presence of astrocytic proliferation and paucity of Clark's column cells in the posterior horns. The same mechanism undoubtedly accounted for dysfunction of the cerebral nerves.

SUMMARY

Clinically the most prominent features of acute (myeloblastic) myelogenous leukemia occurring in a man aged 39 were evidence of peripheral injury to cranial nerves and flaccid paraplegia of the lower extremities. Invasion of nerve roots by the leukemic cells was of principal interest pathologically and is thought to account for the bizarre manifestations seen during life.

IMPROVED METHOD OF STAINING WITHIN TISSUES. LEPTOTRICHES OF PARINAUD'S CONJUNCTIVITIS AND GRAM-POSITIVE MICRO-ORGANISMS

F. H. VERHOEFF, M.D., BOSTON

Judging by my own experience, it is always possible by means of the staining method¹ described by me in 1913 to demonstrate leptotriches in any section which contains one or more of the characteristic foci of leptotrichosis conjunctivae² (Parinaud's conjunctivitis). Assuming that this disease is as frequent in many other localities as it is in Boston (two or three cases a year), failure by other investigators to find these micro-organisms has often been due to the employment of faulty technique. Judging by sections that have been sent to me, a common error is failure to exercise sufficient care in making the biopsy. Only a small bit of tissue need be excised, but since the leptotriches can be readily found only in the foci of macrophages it is essential to include at least one of the gray areas, preferably the largest, that can be seen just beneath the surface of the lesion.

Since the leptotriches of leptotrichosis conjunctivae as they occur in the tissues are completely decolorized by the ordinary Gram or Gram-Weigert method, strictly speaking they may be said to be gram negative. Yet in a sense they are gram positive, since after they are stained in methyl rosaniline the use of compound solution of iodine is necessary to prevent their decolorization by the procedure I have employed. The essential difference between this procedure and the Gram method lies in the successive employment of different solvents for brief periods of time. If alcohol alone, as in the ordinary Gram method, or aniline alone, as in the Gram-Weigert method, is used as the solvent, by the time the tissues are sufficiently decolorized the leptotriches are completely decolorized. In my method, before

From the Howe Laboratory of Ophthalmology, Harvard Medical School, and the Massachusetts Eye and Ear Infirmary.

1. Verhoeff, F. H.: Parinaud's Conjunctivitis: A Mycotic Disease Due to a Hitherto Undescribed Filamentous Organism. *Arch. Ophthalm.* 42: 345, 1913.

2. Verhoeff, F. H.: Observations on Parinaud's Conjunctivitis, Leptotrichosis Conjunctivae, *Am. J. Ophthalm.* 1: 705 (Oct.) 1918.

the micro-organisms become decolorized to an important extent by alcohol the sections are transferred to a different kind of solvent. This washes away the alcohol and further decolorizes the tissues, but before it can permeate and decolorize the leptotriches the sections are transferred to oil, which checks the decolorization. Further differentiation is similarly obtained by transferring the sections alternately to oil and alcohol. Success of this method apparently means that to the solvents the leptotriches are less permeable than the surrounding tissues.

In my original method chloroform was employed as one of the solvents. Recently Mr. Thomas Blake, technician in the Howe Laboratory, on his own initiative has tried other solvents as substitutes for chloroform, namely orthochloroaniline, tetrachloroethylene, methyl aniline, carbon tetrachloride and trichloroethylene. We have found that of these, trichloroethylene provides certain advantages over chloroform. The chief advantages are that it lessens the danger of overdecolorization and causes few if any precipitates in the sections. When precipitates occur, they may be removed by the subsequent treatment without danger of decolorization of the leptotriches. Another advantage is that it renders the method as satisfactory after fixation with Zenker's solution as after fixation with solution of formaldehyde. By the chloroform method, we had found it extremely difficult after fixation with solution of formaldehyde to avoid complete decolorization of the leptotriches. We have found that in the new method the time of staining with methyl rosaniline can be reduced to two minutes. The chief disadvantage of the trichloroethylene is that it is apt to leave the tissue cells and infiltrating cells deeply stained, so that the masses of leptotriches may not be so easily recognized under low magnification as when chloroform is used. This, however, is offset by the fact that the leptotriches are more deeply stained. Another disadvantage is that trichloroethylene is decomposed by exposure to light and when not in use must therefore be kept in the dark.

The details of the modified Gram stain as now employed in this laboratory are as follows:

Fix fresh tissue in Zenker's solution or solution of formaldehyde.

Embed in celloidin or paraffin. Celloidin sections are the more readily manipulated.

Cut sections as thin as possible, not more than 10 microns in thickness.

Stain sections in hematoxylin and eosin.

Mount, examine and select sections that contain the largest foci of macrophages.

By the aid of xylene remove the selected sections from the slide and wash in oil of thyme, then in 95 per cent alcohol and then in water. (Hematoxylin may be removed by acid alcohol, but this is not necessary.) If large foci of macrophages have been found, adjacent unstained sections will undoubtedly also contain them and may therefore be used instead.

The solvents now to be used are placed in small receptacles such as ordinary salt cellars. Celloidin sections are to be immersed in these. In the case of paraffin sections the solutions are to be dropped on the slides by means of eye droppers. Water is placed in large finger bowls.

Place the celloidin section from the water on a slide. Wipe away any excess of water and drop on the section Stirling's crystal violet (methyl rosaniline 5 Gm., 95 per cent ethyl alcohol 10 cc., aniline 2 cc., water 88 cc.). After two minutes,

Float the section from the slide into a bowl of water. Wash in several changes of water; this requires about two minutes.

Immerse in compound solution of iodine, from twenty to sixty seconds (iodine 1 Gm., potassium iodide 2 Gm., water 100 cc.).

Wash in water and transfer to

95 per cent alcohol. Stir the section around until the stain begins to come out freely, about five seconds, and then transfer quickly to

Trichloroethylene.³ Stir the section around until the color ceases to come out freely, about ten seconds; transfer to

Oil of thyme one minute, then to

95 per cent alcohol five seconds and again to

Oil of thyme. Examine on the slide under the low power of the microscope. If precipitates are present, or differentiation

is insufficient, differentiate further by alternate immersions in 95 per cent alcohol and oil of thyme, five seconds each.

Wash in xylene, two changes and

Mount in cedar oil on a slide.

By this method the leptotriches should be deeply stained and easily recognizable when occurring, as is usually the case, in masses. Isolated leptotriches will probably not be recognized by inexperienced observers. If no leptotriches are visible, other structures such as fibrin, granules of mast cells and chromatin may possibly be mistaken for them by those who have never seen these micro-organisms. When leptotriches are present in masses, however, their appearance is so characteristic and so different from any other structures in the tissues that they are easily identified.

For the staining of gram-positive micro-organisms and fibrin within tissues, I have found this method (and also the chloroform method) superior to the ordinary Gram or Gram-Weigert method. In the case of gram-positive bacteria, if desired, the differentiation can be carried further in each of the solvents until the fibrin is decolorized. In the only case of sporotrichosis in which I have applied this method to sections I succeeded in staining the sporotriches. By this method I have been able to stain meningococci within sections in spite of the fact that these cocci are gram negative. Possibly the method may be found useful for the demonstrating of still other gram-negative micro-organisms within tissues.

243 Charles Street.

Council on Pharmacy and Chemistry

NEW AND NONOFFICIAL REMEDIES

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION.

PAUL NICHOLAS LEECH, Secretary.

EUCATROPINE HYDROCHLORIDE (See New and Nonofficial Remedies, 1940, p. 113).

Eucatropine Hydrochloride-Werner.—A brand of eucatropine hydrochloride-N. N. R.

Manufactured by the Werner Drug & Chemical Co., Cincinnati, Ohio. No U. S. patent or trademark.

PROCAINE HYDROCHLORIDE-UPJOHN (See New and Nonofficial Remedies, 1940, p. 83).

The following dosage forms have been accepted:

Hypodermic Tablets Procaine Hydrochloride 0.05 Gm. (3/4 grain). Each tablet contains procaine hydrochloride 0.05 Gm. (3/4 grain) with sodium chloride as a base. One tablet dissolved in 1 cc. of distilled water makes a 5 per cent solution of procaine hydrochloride.

Hypodermic Tablets Procaine Hydrochloride 0.02 Gm. (1/2 grain) with Epinephrine 0.025 mg. (1/2,500 grain): Each tablet contains procaine hydrochloride 0.02 Gm. (1/2 grain), epinephrine 0.025 mg. (1/2,500 grain), sodium chloride 0.013 Gm., benzoic acid 0.3 mg., sodium bisulfite 0.125 mg. and boric acid 2.27 mg. One tablet dissolved in 1 cc. of distilled water makes a 2 per cent solution of procaine hydrochloride.

SODIUM CACODYLATE (See New and Nonofficial Remedies, 1940, p. 109).

The following further dosage forms have been accepted:

Cheplin's Solution of Sodium Cacodylate with Benzyl Alcohol 0.05 Gm. (3/4 grain), 30 cc. vial: Benzyl alcohol 1 per cent is added for its local anesthetic effect.

Cheplin's Solution of Sodium Cacodylate with Benzyl Alcohol 0.2 Gm. (3 grains), 30 cc. vial: Benzyl alcohol 1 per cent is added for its local anesthetic effect.

Cheplin's Solution of Sodium Cacodylate with Benzyl Alcohol 0.3 Gm. (5 grains), 30 cc. vial: Benzyl alcohol 1 per cent is added for its local anesthetic effect.

Cheplin's Solution of Sodium Cacodylate with Benzyl Alcohol 0.5 Gm. (7 1/2 grains), 30 cc. vial: Benzyl alcohol 1 per cent is added for its local anesthetic effect.

Cheplin's Solution of Sodium Cacodylate with Benzyl Alcohol 0.065 Gm. (1 grain), 1 cc.: Benzyl alcohol 1 per cent is added for its local anesthetic effect.

THIAMIN CHLORIDE (See New and Nonofficial Remedies, 1940, p. 528).

The following dosage forms have been accepted:

Tablets Thiamine Hydrochloride, 5 mg.

Prepared by Frederick Stearns & Co., Detroit, Mich.

Tablets Thiamine Hydrochloride, 10 mg.

Prepared by Frederick Stearns & Co., Detroit, Mich.

3. Obtainable from the Eastman Kodak Company.

SATURDAY, NOVEMBER 2, 1940

THE PLATFORM OF THE AMERICAN MEDICAL ASSOCIATION

The American Medical Association advocates:

1. The establishment of an agency of the federal government under which shall be coordinated and administered all medical and health functions of the federal government exclusive of those of the Army and Navy.
2. The allotment of such funds as the Congress may make available to any state in actual need, for the prevention of disease, the promotion of health and the care of the sick on proof of such need.
3. The principle that the care of the public health and the provision of medical service to the sick is primarily a local responsibility.
4. The development of a mechanism for meeting the needs of expansion of preventive medical services with local determination of needs and local control of administration.
5. The extension of medical care for the indigent and the medically indigent with local determination of needs and local control of administration.
6. In the extension of medical services to all the people, the utmost utilization of qualified medical and hospital facilities already established.
7. The continued development of the private practice of medicine, subject to such changes as may be necessary to maintain the quality of medical services and to increase their availability.
8. Expansion of public health and medical services consistent with the American system of democracy.

THE PHYSICAL STANDARDS UNDER SELECTIVE SERVICE

In the section of THE JOURNAL devoted to medical-military preparedness in this issue appears an abstract of the standards which have been adopted to guide the physicians who will be associated with local selective service boards and medical advisory boards and also the specialists who will be associated with the induction boards. The manual is essentially the same for all of these groups. Every physician will find it informative to study carefully these standards, bearing in mind that the purpose is to select men capable of undergoing military training and not essentially an inventory throughout the nation of the health of men from 21 to 35 years of age.

In the selective service of 1917 each of the young men who appeared before a local board was given a physical examination. Under the present system only

those men will be physically examined who have been found suitable for training after exemption has been considered from the point of view of marriage, essential occupation or some of the many other reasons which have been considered sufficient to exempt the young man from military service. The selective service organization has prepared six pamphlets in which the various aspects of the work of the selective service boards are discussed. Especially noteworthy is the excellent section on malingering in the pamphlet on physical standards, which will find application not only in the work of the selective service boards but no doubt in the practice of every physician who examines any number of persons for insurance, for industry, or for educational or other purposes.

As has been previously mentioned, a final examination, which is the one made by the induction board, will be necessary before any young man is sent for training to a camp or cantonment. That examination will be made by a group of specialists who will be given the necessary facilities and time for a study much more comprehensive than can be made by either the examiner for the local selective service board or the medical advisory board.

Especially noteworthy also are the new regulations regarding serologic examination, not duplicated, as far as we know, in any other country or by this country in any previous emergency. Special interest taken by the United States Public Health Service in this phase of health or disease is reflected in this procedure. Every young man who receives a physical examination by a physician associated with the selective service board will have a serologic test. If the test is positive, it is to be repeated. Apparently those who have syphilis with remedial manifestations—except those with cerebrospinal, cardiovascular or visceral syphilis—will be placed in class 1A, which is the group considered to be qualified for general military service. Presumably the decision as to how much attention is to be given to the presence of syphilis will rest with the military authorities after induction into the service.

EXPERIMENTAL HYPERTENSION

The probability of developing therapeutic measures to cure or ameliorate a clinical condition is greatly enhanced when it is possible to produce a similar situation experimentally in animals. Such studies have been of inestimable practical value and it is not surprising, therefore, in view of the importance of the condition, that much investigative effort has been expended in an effort to produce experimentally in animals an elevation of the blood pressure which might be comparable to clinical hypertension. Much information has been accumulated as a result of research in this field; in this connection a recent review by Blalock¹ is timely and merits consideration.

1. Blalock, Alfred: *Physiol. Rev.* 20:159 (April) 1940.

In general, research activity into the cause of hypertension has followed along two lines, one involving a study of hypertension effected by procedures carried out on the central nervous system, the other dealing with experimental hypertension of renal origin. With regard to the hypertension that is generally considered to be of nonrenal origin, it seems certain that section of the moderator nerves results in an elevation of the blood pressure, usually of temporary nature, although it may sometimes be sustained. Whether or not there is any relationship between this type of hypertension and the clinical manifestation in man is, of course, problematic. Although it is true that increased vasoconstriction is present in both essential hypertension and experimental hypertension due to removal of the moderator nerves, it does not necessarily follow that essential hypertension is due to a derangement of the carotid sinus and aortic depressor nerve mechanisms. Indeed, it has been pointed out by Nowak and Walker² that the similarity lies in the end result rather than in the cause. The elevation of blood pressure effected by increased intracranial pressure has also been studied. However, a review of the pertinent literature¹ evokes the impression that this type of hypertension cannot be produced with great regularity and is usually not lasting. Cerebral anemia produced by progressive occlusion of the various cerebral arteries also results in an elevation of the blood pressure.² Nevertheless it is doubtful whether this method is of practical value as a consistent means of producing chronic hypertension.

At the present time interest is centered particularly on experimental hypertension of renal origin. The problem has been approached experimentally from many different angles. Thus, some investigators have studied the production of a condition resembling glomerulonephritis in animals, many have investigated the effect on blood pressure of damage to the kidneys or of nephrectomy, including subtotal nephrectomy by various methods, and other investigators have carried out research on the effect of occlusion of the ureters or of constriction of the renal arteries. Hypertension resulting from constriction of the renal arteries is of particular interest, and fundamental work in this connection has been carried out by Goldblatt³ and his associates. Depending on the degree of constriction of the renal arteries, hypertension either with or without a disturbance of renal function may be produced. The observation that bilateral renal ischemia may result in a persistent elevation of the blood pressure has made possible the regular experimental production in animals of a condition analogous to one encountered in cases in man. Within the past few years the mechanism which is responsible for the production of hypertension by renal ischemia has been intensively investigated. Evidence has been accumulated which indicates strongly that it is not a nervous mechanism. Similarly, it would

seem that although the endocrine glands are important in determining the degree of response they are not essential for the development of renal hypertension, associated with renal ischemia. The possibility that a chemical mechanism is involved in this increase in blood pressure is at present receiving considerable attention. Experimental evidence is available which supports the view that the hypertension associated with renal ischemia is the result of the action of a pressor substance which is formed in the kidney and enters the blood stream. Moreover, experiments indicating the exclusion of other possible mechanisms also argue indirectly in favor of a humoral factor. It is interesting to note that renin, a renal pressor substance (which is now believed to require the presence of an activator to be effective), was first described more than four decades ago.

Although it is, of course, to be granted that some types of hypertension are of nonrenal origin, most instances of experimental and probably of clinical hypertension, according to Blalock, would seem to be related to some abnormality in the function of the kidneys. In this connection it is interesting to refer to Karsner's⁴ recent statement that failure to demonstrate any signs of renal incompetence in life is not indicative of the absence of arteriolar disease of the kidneys. In any case investigations on experimental hypertension have afforded much valuable information and will certainly continue to do so.

Current Comment

IS THERE A SHORTAGE OF INTERNS?

Not infrequently one hears that hospitals cannot secure acceptable interns because there are not enough to go around and that the number of graduates from approved medical schools is insufficient to supply the needs of the hospitals which offer to train interns. Granted that there can never be an exact correspondence between the supply and the demand for interns, it seems worth while to consider whether the available medical graduates are now distributed in accordance with the legitimate needs of the institutions they serve. In many of the best teaching hospitals the house staff bears a ratio to the annual admissions of 1:400 or 1:450. In private institutions the ratio may be as high as 1:600 or 1:800. In the New York Metropolitan area there are at least forty-five hospitals with a house staff in excess of 1:400, ten of them in excess of 1:200. Why do these hospitals employ so many more interns and residents than other institutions which maintain unimpeachable educational standards? Apparently all the hospitals which operate with an excessively large house staff also maintain an ambulance service, and a substantial part of the intern's time is devoted to ambulance duty. For example, in one of the city hospitals each intern is required to spend four months out of twelve "riding the ambulance." In a private hospital the junior interns spend half their time in the ambulance service.

2. Nowak, S. J. G., and Walker, I. J.: *New England J. Med.* 220: 269 (Feb. 16) 1939.

3. Goldblatt, Harry: *Ann. Int. Med.* 11:69 (July) 1937.

4. Karsner, H. T.: *Internat. Clin.* 2:1 (June) 1938.

If ambulance calls were in reality medical emergencies this experience might be of value to the intern; most of the calls, however, are for transfers or other services which contribute nothing to the education of the physician. These functions could as well be performed by nurses or orderlies; certainly such experience is out of place in an accredited program for the training of interns. Elimination of this undesirable feature of the intern's education (?) in New York City would release a substantial number of interns for service elsewhere.

DYSENTERY AND ESCHERICHIA COLI DEFICIENCY

According to Razi Maner,¹ staff physician of the Turkish army, the colon bacillus is an essential part of the normal defense against enteric infections. From this he concludes that typhoid, paratyphoid and dysentery infections are essentially due to a qualitative deficiency in normal intestinal flora. The present clinical interest in bacterial antagonism dates from Nissle's² study of the "antagonistic index" between *Escherichia coli* and *Eberthella typhi*. He found that many strains of the colon bacillus are able to kill or completely inhibit the growth of typhoid bacilli when the two antagonistic species are inoculated together in the same culture medium. The ratio of growth of the antagonistic microorganisms was designated by him as the "antagonistic index." With many strains of *Escherichia coli* the index was 100:0, no viable typhoid bacilli being demonstrable in the resulting mixed culture. Weaker strains of the colon bacillus gave indexes varying from 100:10 to 100:103 or even as low as 100:4,050. He found that the index is a stable characteristic of different colon strains, being retained without appreciable change during many months of artificial cultivation. Gundel,³ Kamada,⁴ Rizzi⁵ and others afterward extended this study to the paratyphoid bacillus, staphylococcus, streptococcus and anthrax bacillus. They found that the colon bacillus is antagonistic to each of these pathogenic forms. Maner's current contribution is a statistical survey of dysentery antagonism. Fifty-four colon strains and three dysentery species were titrated for their antagonistic indexes. In his hands the antagonistic index is considerably stronger against dysentery bacilli than that against organisms previously studied. The Turkish clinician found that *Escherichia coli* isolated from dysentery stools is invariably deficient in antagonistic characters, in all cases the symptoms being associated with a qualitative *Escherichia coli* deficiency. He emphasizes the fact, however, that much more extensive statistical evidence must be collected before qualitative *Escherichia coli* deficiency can be accepted as the essential etiologic factor in bacillary dysentery. The possibility of preventing or treating enteric disease by implantation of highly antagonistic strains of *Escherichia coli* is now under investigation in European clinics.

CAPTAIN ENGLAND—YELLOW FEVER VOLUNTEER—RETIRES

Some forty years has passed since the United States Army Yellow Fever Commission conducted its famous experiments in Cuba. Previously epidemics of yellow fever had prevailed in the United States and had taken many thousands of lives. When Major Reed and his associates began the experiments in Cuba, yellow fever still was a serious threat to American soldiers. Reed called for volunteers to submit to experiments designed to discover the method of transmission of yellow fever. Fourteen volunteers were bitten by mosquitoes which had fed on patients sick with yellow fever, and all became ill. Six volunteers were infected by the injection of blood from patients ill of yellow fever and all became ill. Two volunteers were given injections of filtered blood serum from yellow fever patients and both became ill. Seven volunteers exposed themselves to fomites but not one became ill. In the last group was Thomas M. England, then a private in the Army Medical Department on duty in the typhoid ward. Now Captain England of the Medical Administrative Corps of the Army, he retired October 31 after forty years of active service. Captain England was born in Chillicothe, Ohio. His service is distinguished not only by participation in the experiments that enabled this country to become free from yellow fever; he remained in Cuba two years longer and then served in the Philippine campaign, for which he was cited for bravery under fire. He also served on the Mexican border in 1916 and went to France in 1918 with the Thirty-Third Division and there was promoted to Captain. He has served since then in the Office of the Surgeon General, at San Francisco, at the Fifth Corps Area headquarters in Columbus, Ohio, and at the corps area headquarters in New York. Captain England now will make his home in Columbus.

RIBOFLAVIN IN THE TUBERCLE BACILLUS

Two years ago, Boissevain and his colleagues¹ of Colorado Springs studied the melting point and absorption spectrum of the fluorescent yellow pigment formed by the tubercle bacillus. Their data suggested a close similarity of this pigment with vitamin B₂ (riboflavin). Street and Reeves² of Yale University School of Medicine have recently supplemented this evidence by a study of the growth response of riboflavin-deficient rats to this pigment. Young albino rats were reared to a stunted growth on a riboflavin-deficient diet and were then given the same diet plus a daily dose of 40 micrograms (0.04 mg.) of the tubercle flavin. Within the limits of the experimental error the growth response to this pigment was identical with the growth response of control rats in which the deficiency diet had been supplemented by a daily addition of 40 micrograms of crystalline riboflavin. The evidence seems complete, therefore, that the yellow fluorescent pigment formed by the tubercle bacillus is identical with riboflavin. From 13 to 19 mg. of this bacterial riboflavin can be isolated from 1 Kg. of dry tubercle bacilli.

MEDICAL PREPAREDNESS

In this section of The Journal each week will appear official notices by the Committee on Medical Preparedness of the American Medical Association, announcements by the Surgeon Generals of the Army, Navy and Public Health Service, and other governmental agencies dealing with medical preparedness, and such other information and announcements as will be useful to the medical profession.

COORDINATING COMMITTEE APPOINTS SUBCOMMITTEES

Subcommittees on medical education, hospitals, industrial medicine, dentistry, nursing and Negro health have been announced by the Health and Medical Committee of the Council of National Defense. The general committee, headed by Dr. Irvin Abell of Louisville, Ky., former President of the American Medical Association, was appointed by President Roosevelt on September 19 to survey and coordinate the medical resources of the country in the interests of national defense.

Announcement of the subcommittees was made by Dr. Abell from his office at the Public Health Service Administration Building in Washington. Dr. C. Sidney Burwell, dean, Harvard Medical School, Boston, was named chairman of the subcommittee on medical education. Other members of this group are Dr. L. R. Chandler, Stanford University Hospital, San Francisco; Dr. Harold S. Diehl, dean of the University of Minnesota Medical School; Dr. Willard C. Rappleye, commissioner of hospitals of the city of New York, and Dr. John H. Musser of the Tulane University of Louisiana School of Medicine, New Orleans.

The subcommittee on hospitals includes Dr. Winford H. Smith, director of Johns Hopkins Hospital, Baltimore, chairman; Rev. Alphonse M. Schwittalla, president, Catholic Hospital Association of United States and Canada, St. Louis; Dr. Malcolm T. MacEachern, associate director of the American College of Surgeons, Chicago; Dr. Claude W. Munger, chairman of the defense committee of the American Hospital Association, New York, and Dr. Nathaniel W. Faxon, superintendent of the Massachusetts General Hospital, Boston.

The subcommittee on industrial medicine was set up with Dr. Clarence D. Selby, medical consultant of General Motors Corporation, Detroit, as chairman. Other members of this subcommittee included Prof. Philip Drinker, Harvard School of Public Health, Boston; Dr. E. C. Holmblad, Chicago; Dr. George M. Smith, Yale University Medical School, New Haven, Conn.; Dr. Lloyd Noland, chief surgeon, Tennessee Coal, Iron and Railroad Company, Fairfield, Ala.; Mr. William P. Yant, Mine Safety Appliance Company, Pittsburgh, and Dr. A. J. Lanza of the Metropolitan Life Insurance Company, New York.

A subcommittee on dentistry was named with the following members: Dr. C. Willard Camalier, Washington, D. C., former president of the American Dental Association, chairman; Dr. John T. O'Rourke, dean of the University of Louisville School of Dentistry; Dr. Leroy M. S. Miner, dean of the Harvard University Dental School, Boston; Dr. Frederick B. Noyes of Chicago and Dr. Guy S. Millbury of San Francisco, former dean of the Dental School of the University of California.

Miss Mary Beard, director of nursing of the American Red Cross, was named chairman of a subcommittee on nursing, and Dr. M. S. Bousfield of the Julius Rosenwald Fund, Chicago, will head a subcommittee on Negro health.

In announcing these subcommittees, Dr. Abell stated that these subcommittees would assist the Defense Council's Medical Committee in coordinating health and medical activities and in "mobilizing the medical resources of the nation for national defense."

Other members of the Health and Medical Committee on national defense as appointed by the President and the National Defense Council are Major General James C. Magee, Surgeon General of the Army; Rear Admiral Ross T. McIntyre, Surgeon General of the Navy; Dr. Thomas Parran, Surgeon General of the United States Public Health Service, and Dr. Lewis H. Weed, chairman of the Division of Medical Sciences of the National Research Council.

The general committee has already had two meetings and, in addition to setting up its various subcommittees, has considered the need for developing research projects dealing with special problems of military medicine and hygiene. Examples of such special problems are finding better methods of treatment of war wounds, exploring the most modern usages of recently discovered chemicals in the treatment and prevention of disease, problems of aviation medicine, and the most effective measures for the control of the venereal diseases.

The committee is also concerned with the necessity for providing health services in areas surrounding military camps and cantonments and with the health and medical problems arising as a consequence of the greatly expanded industrial development in certain regions of the country.

The committee hopes to find ways and means of providing adequate medical facilities and personnel, including hospitals, physicians and surgeons, dentists and nurses for the armed forces of the nation without the serious disruption of these essential services on the home front. It is enlisting the services and coordinating the efforts of both governmental and private agencies in building up the health and medical facilities of the nation as part of the present peacetime mobilization.

EXAMINATION FOR ARMY MEDICAL CORPS

An examination of applicants for appointment as first lieutenant, Medical Corps, U. S. Army, will be held within the continental limits of the United States, March 10-13, 1941, inclusive. Applications and requests for information concerning this examination should be addressed to the Adjutant General, U. S. Army, Washington, D. C. Applications received after Feb. 20, 1941, will not be considered.

PHYSICAL STANDARDS UNDER SELECTIVE SERVICE

The physical standards governing the physical examination of registrants by the examining physicians of the Selective Service system are the same as those which have been developed by the United States Army Medical Corps for the examination of selected men at Army and Navy induction stations. The objective is to procure men who are physically fit for the rigors of general service. In brief the regulations say:

The registrant must be able to see well; have comparatively good hearing; have a heart able to withstand the stress of physical exertion; be intelligent enough to understand and execute military maneuvers, obey commands, and protect himself; and be able to transport himself by walking as the exigencies of military life may demand. Examining physicians will accordingly so construe these standards that the objective stated above may be realized.

Registrants are to be placed in three classes according to physical standards, which will make them acceptable for general military service, for limited military service or reject them for any military service. The physicians of the draft boards are to make a complete examination and to record minor defects as well as disqualifying defects. The Medical Advisory Boards are to make additional and repeated examinations and special reports. In localities where there is no provision for serologic and other laboratory work, the examining physicians will consult municipal or state health authorities, the United States Public Health Service or other federal agencies.

The examiners are not permitted to give an anesthetic to a registrant without his voluntary consent for the purpose of examination or to aid in the diagnosis of defects.

The final decision as to the acceptance or rejection of men will, of course, rest with the physicians at the induction stations.

Reportable diseases are to be notified to appropriate civil authorities when found by the examining physicians of the Selective Service boards.

Venereal Disease

The regulations regarding venereal disease follow:

a. Whenever the history or the physical examination of a registrant indicates the possibility of venereal disease, the matter shall be thoroughly investigated, employing such additional examinations and laboratory tests as are deemed necessary to determine the presence of disqualifying sequelae or of contagiousness. A serological test for syphilis shall be made on every registrant as part of his physical examination. The blood specimen will be taken by the examining physician in containers furnished by the State Health officer and forwarded to the State Laboratory or other laboratory designated by State Selective Service Headquarters, together with the accomplished forms prescribed within the State for such purpose. A second serological test shall be completed promptly and prior to his call for induction on every registrant whose first test is reported positive. The dates and results of such examinations and tests shall be noted on the Report of Physical Examination (Form 200).

b. A diagnosis of syphilis shall not be made on the basis of a single positive serological test in the absence of definite clinical manifestations of the disease.

c. A diagnosis of latent syphilis shall be made on a registrant who has no clinical manifestations of the disease, but whose blood serum has been found positive by a second serological test performed under these regulations and within three months of the first positive serological examination.

d. Syphilis shall be considered contagious only in the presence of skin or mucous membrane lesions manifested within five years from the date of infection.

Each board is to have one physician, but additional appointments may be made if more than one examining physician is needed. An examining physician is not permitted to examine for a board any registrant who is a first cousin or a closer relation, either by blood or by marriage, or who is an employer or an employee, or who stands in the relation of superior or subordinate in connection with any employment, or is a partner or close business associate of the physician. In such instances the board may request another physician or the use of the examining physician of another board.

Each of the Advisory Boards is to have, if practicable, internists, eye, ear, nose and throat specialists, orthopedists, surgeons, psychiatrists, clinical pathologists, radiographers and dentists.

Cases Sent to Medical Advisory Boards

The local board will send registrants to the nearest Medical Advisory Board whenever the examining physician or the government appeal agent so requests or whenever a majority of the local board is dissatisfied with the conclusions of the examining physician.

Standards and Minimum Acceptable Measurements of Height, Weight and Circumference of Chest

Standard			Minimum	
Height, Inches	Weight, Pounds	Chest Measurement at Expiration, Inches	Weight, Pounds	Chest Measurement at Expiration, Inches
60	116	31½	105	28¾
61	119	31½	107	29
62	122	31¾	109	29¼
63	125	32	111	29½
64	128	32¾	113	29¾
65	132	32¾	115	30
66	136	32¾	117	30¼
67	140	33	121	30½
68	144	33¾	125	30¾
69	148	33¾	129	31
70	152	33¾	133	31¼
71	156	34	137	31½
72	160	34¼	141	31¾
73	164	34½	145	32
74	168	34¾	149	32¼
75	172	35	153	32½
76	176	35¼	157	32¾
77	180	35½	161	33
78	184	35¾	165	33¼

Any one with an infectious disease will obviously not be selected for military service. If, however, he has recovered from such a condition and has not had any complications which remain permanently, he would be inducted. If he is drawn in the selective service at the time when he is ill, his acceptance is merely deferred until final examination shows that he has recovered.

This applies also to malaria, hookworm or to any recent injury such as wound of the hand. The existence of such an injury will not bar the young man from service but would merely defer his acceptance.

On the other hand, the presence of cancer or any other malignant disease, of active tuberculosis, leprosy, rheumatic fever or severe infection of the bones—or even severe hookworm infection, which might require months

for recovery—would be sufficient to put the registrant in the class that is not to be called for any type of military service.

In the accompanying table are given standards and minimum acceptable measurements of height, weight and the circumference of the chest.

Any one who falls within these standards is considered suitable for general military service, even one whose weight is greater than the standard indicated for the height, provided the overweight is not sufficient to interfere with military training. Thus the mere fact that a man is overweight will not in itself bar him from military service. Such a man may be selected for limited service or special service, provided he is not otherwise mentally and physically unfit.

The army cannot use men who are "outsize." The man who is less than 60 inches in height or less than 105 pounds in weight is simply too small for the army; the giant has the same trouble. Any one who is more than 6 feet 6 inches tall or whose weight is far out of proportion to his height is also considered to be outsize and will not be inducted into regular military service.

The examining board is given a good deal of discretion in matters of weight and height. If, in the opinion of the board, proper food and physical training will make a man capable of giving service, he is likely to be inducted into the service and to get just the proper food and training necessary to make him a physically fit specimen.

Eyes

Vision.—To determine the acuity of vision, place the person under examination with his back to a window at a distance of 20 feet from the test types. Examine each eye separately, without glasses, covering the other eye with a card (not with the hand). The registrant is directed to read the test types from the top of the chart down as far as he can see, and his acuity of vision is recorded for each eye, with the distance of 20 feet as the numerator of a fraction and the size of the type of the lowest line he can read correctly as the denominator. If he reads the 20 feet type correctly, his vision is normal and recorded 20/20; if he does not read below the 30 feet type, the vision is imperfect and recorded 20/30; if he reads the 15 feet type, the vision is unusually acute and recorded 20/15, and so on.

Class 1-A.—*a.* Normal vision. *b.* 20/100 in each eye without glasses, if correctable with glasses to 20/40 bilateral. *c.* Conditions due to iridectomy or other operation upon the eye, if the condition for which the operation was performed has been relieved and the vision is within or above the minimum standard requirements. *d.* Slight nystagmus. *e.* Slight conjunctivitis. *f.* Chronic simple conjunctivitis occurring in regions where trachoma is not prevalent and if easily remediable. *g.* Slight adhesion of the lids to the eyeball. *h.* Small pterygium. *i.* Strabismus which does not interfere with vision. *k.* Color blindness. *l.* Exophthalmos if not of such degree as to have led to, or threatened, corneal ulceration, and provided hyperthyroidism is excluded.

Class 1-B.—*a.* A minimum vision of 20/400 in each eye without glasses, if correctable with glasses to 20/40 in either eye. *b.* Loss of one eye or blindness in one eye not due to progressive organic change, with vision in the other eye of not less than 20/200 correctable to not less than 20/40. *c.* Superficial corneal ulcer, provided acceptance is deferred until ulcer is healed without disqualifying impairment of vision. *d.* The following conditions, if mild: (1) Chronic conjunctivitis not trachomatous. (2) Inversion of eyelids. (3) Eversion of eyelids. (4) Ptosis interfering with vision. (5) Trichiasis. (6) Epiphora. (7) Chronic blepharitis. (8) Extensive pterygium. (9) Chronic dacryocystitis. (10) Blepharospasm. (11) Diplopia due to paralysis of ocular muscles of one eye, if mild.

In Class 4 are defects such as the following: *a.* Vision less than the minimum requirements for special and limited military

service. *b.* Disfiguring cicatrices of eyes. *c.* Lagophthalmus, if associated with signs of hyperthyroidism. *d.* Pronounced exophthalmus. *e.* Chronic keratitis. *f.* Chronic recurrent inflammatory disease of the globe. *g.* Deep chronic ulcer of cornea. *h.* Any active disease of the retina, choroid, or optic nerve. *i.* Detachment of the retina. *j.* Marked nystagmus. *k.* Glaucoma. *l.* Diplopia due to paralysis of extrinsic ocular muscle, unless mild in degree. *m.* Abnormal conditions of eyes due to disease of the brain. *n.* Trachoma.

There are provided for the physicians of the boards complete instructions regarding the detection of malinger and other methods of examination, also instructions regarding retinoscopy.

Ears

Examination for Disease.—The external ears and mastoid region will be examined by inspection and, if necessary, the mastoid region by palpation. The external auditory canal and membrana tympani will be examined by reflected light or by a self-illuminating otoscope.

Determination of Auditory Acuity.—Acuity of hearing will be determined by the low conversational voice test and by the audiometer when indicated. To determine the acuity of hearing, place the registrant facing at right angles to the assistant, 20 feet distant, with ear to be tested toward assistant, and direct him to repeat promptly the words spoken by the assistant. If the registrant cannot hear the words at 20 feet, the assistant should approach foot by foot, using the same tone of voice, until the words are repeated correctly. Examine each ear separately, closing the other ear by pressing the tragus firmly against the meatus; the examiner may face the same direction as the registrant and close one of his own ears in the same way as a control. The assistant should speak in a low conversational voice (not a whisper), just plainly audible to the examiner, and should use numerals, names of places, or other words or sentences until the condition of the registrant's hearing is evident. The acuity of hearing should be expressed in a fraction, the numerator of which is the distance in feet at which the words are heard by the normal ear; thus 20/20 indicates a normal hearing, 10/20 partial hearing of a degree indicated by the fraction, that is, the registrant only hears at 10 feet distance the words which a normal ear hears at 20 feet. The duties of the examiner and assistant may be reversed if desired. If any doubt arises as to the correctness of the answer given, the registrant may be blindfolded and a watch be used to determine the distance at which it can be heard, care being taken that the registrant does not know the distance from the ear at which it is being held. The watch if used should be one whose ticking strength has been tested by determining the distance at which it can be heard by a normal ear. The audiometric examination will be conducted according to the method prescribed by the manufacturers of the instrument employed, and the findings as recorded on the prescribed form will be forwarded for file with the examination report.

In Class 1-A are *a.* Normal hearing. *b.* Hearing in each ear of 10/20 or better.

In Class 1-B are *a.* Hearing in one or both ears less than 10/20 but more than 5/20. *b.* Loss of one or both external ears, if the registrant has followed a useful vocation in civil life and the deformity is not too greatly disfiguring.

In Class 4 are defects such as *a.* Hearing less than the minimum hearing prescribed under class 1-B. *b.* Chronic purulent otitis media, with or without mastoiditis. *c.* Chronic perforation of membrana tympani.

Instructions are also provided for testing for malinger with directions for Erhard's test and the Chiman-Moos test.

Mouth, Nose, Fauces, Pharynx, Trachea, Esophagus and Larynx

In Class 1-A are *a.* Normal conditions of the mouth, nose, fauces, pharynx, larynx, trachea and esophagus. *b.* Enlarged tonsils. *c.* Adenoids. *d.* Small benign tumors of the nasal and

buccal mucous membrane. *e.* Deviation of the nasal septum or enlarged turbinates which do not seriously interfere with nasal breathing. *f.* Acute primary sinusitis, provided the acceptance of the registrant is temporarily deferred for reexamination, if after a reasonable time the sinusitis has disappeared. *g.* Laryngitis manifested by hoarseness, laryngeal cough, and congestion of the vocal cords, confirmed by laryngoscopy, unless tuberculous or malignant. *h.* Alleged stricture of the esophagus which is unattended by evidence of organic disease of the esophagus as shown by a fluoroscopic examination while the registrant is swallowing a barium mixture. *i.* Perforation of hard palate, if not associated with a disqualifying disease. *j.* Moderate deformity of the structures of the mouth which does not seriously interfere with mastication or speech. *k.* Hay fever, unless severe.

In Class 1-B are *a.* Deviation of the nasal septum, which markedly interferes with nasal breathing. *b.* Aphonia, with attendant conditions, which disqualify for general military service, if the registrant has followed a useful vocation in civil life. *c.* Hay fever, if severe.

In Class 4 are defects such as *a.* Irremediable deformities of the mouth, throat, and nose which interfere with the mastication of ordinary food, with speech, or with breathing. *b.* Destructive syphilitic diseases of the mouth, nose, throat, larynx, or esophagus, if severe in degree. *c.* Laryngeal paralysis, due to pressure from aneurysm or tumor. *d.* Permanent tracheostomy. *e.* Stricture of the esophagus. *f.* Permanent gastrostomy. *g.* Chronic sinusitis of the accessory sinuses of the nose, unless mild in degree. (The diagnosis should be established on chronic nasal discharge, presence of large nasal polypi, and other signs and symptoms reinforced by transillumination or x-ray examination, or both.) *h.* Chronic atrophic rhinitis with offensive odor (ozena).

Teeth

In Classes 1-A and 1-B are *a.* Class 1-A.—(1) Normal teeth and gums. (2) A minimum of three serviceable natural masticating teeth above and three below opposing and three serviceable natural incisors above and three below opposing. (Therefore, the minimum requirements consist of a total of six masticating teeth and of six incisor teeth.) All of these teeth must be so opposed as to serve the purpose of incision and mastication. (3) Definitions: (*a.*) The term "masticating teeth" includes molar and bicuspid teeth, and the term "incisors" includes incisor and cuspid teeth. (*b.*) A natural tooth which is carious (one with a cavity), which can be restored by filling, is to be considered as a serviceable natural tooth. (*c.*) Teeth which have been restored by crowns or dummies attached to bridgework, if well placed, will be considered as serviceable natural teeth when the history and the appearance of these teeth are such as clearly to warrant such assumption. (*d.*) A tooth is not to be considered a serviceable natural tooth when it is involved with excessively deep pyorrhea pockets, or when its root end is involved with a known infection that has or has not an evacuating sinus discharging through the mucous membrane or skin. *b.* Class 1-B.—Insufficient teeth to qualify for class 1-A, if corrected by suitable dentures.

In Class 4 are *a.* Irremediable disease of the gums of such severity as to interfere seriously with useful vocation in civil life. *b.* Serious disease of the jaw which is not easily remediable and which is likely to incapacitate the registrant for satisfactory performance of general or limited military service. *c.* Extensive focal infection with multiple periapical abscess, the correction of which would require protracted hospitalization and incapacity. *d.* Extensive irremediable caries.

Skin

Class 1-A.—*a.* Normal skin. *b.* Acute nonexanthematous and noncommunicable diseases of the skin which ordinarily run a temporary course. *c.* Diseases which are trivial in character and which do not interfere with the general health and are not incapacitating. Among these common and usually trivial diseases may be enumerated (1) Acne. (2) Anomalies of pigmentation. (3) Scars not extensive, disfiguring, nor incapacitating in character. (4) Condylomas which are not extensive. (5) Staphylococcal and streptococcal skin infections. (6) Acute eczemas.

(7) Nevi which are not greatly disfiguring. (8) All forms of pediculosis. (9) All forms of ringworm, unless severe and not easily remediable. (10) Scabies, unless severe and not easily remediable. (11) Mild and not extensive psoriasis. (12) Warts. *d.* Simple ulcers or other acute defects of the skin which are easily curable. *e.* Pilonidal cyst or sinus if unattended with disease of the bone, as shown by x-ray examination. *f.* Unusual skin defects should arouse suspicion of self-inflicted lesions (dermatitis factitia).

Class 1-B.—Such defects as chronic diseases of the skin, which disqualify for general military service, if the registrant has successfully followed a useful vocation in civil life.

Class 4.—Serious or incapacitating skin disorders such as *a.* Chronic skin diseases or chronic ulcers of the skin which are so severe or so disfiguring as to incapacitate the registrant for the duties of a soldier or so disfiguring as to render the registrant objectionable in common social intercourse. *b.* Actinomycosis. *c.* Dermatitis herpetiformis of long duration. *d.* Epidermolysis bullosa. *e.* Forms of generalized dermatitis of long duration. *f.* Allergic dermatoses if severe and not easily remediable. *g.* Mycosis fungoides. *h.* Chronic pemphigus. *i.* Lupus vulgaris. *j.* Syphilitic lesions ulcerative in character showing much destruction of tissue which if healed would be unsightly or so scarring as to incapacitate the registrant for military service. *k.* Elephantiasis.

Head

Class 1-A.—*a.* Normal skull. *b.* Moderate deformities of the bones of the skull of the character of depressions, exostoses, and the like and unassociated with evidence of disease of the brain, spinal cord or peripheral nerves, and which would not prevent the registrant from wearing military headgear. *c.* Defects which are apparently temporary in character due to recent injuries. (This includes contusions and other wounds of the scalp and concussion. Registrants with these defects should have the final examination temporarily deferred.)

Class 1-B.—Osseous defects due to decompression or trephine of the skull, if asymptomatic and unassociated with bulging at the site of operation.

Class 4.—*a.* Deformities of the skull of the nature of depressions, exostoses, etc., of a degree which will prevent the registrants from wearing military headgear. *b.* Deformities of the skull of any degree associated with evidences of disease of the brain, spinal cord, or peripheral nerves. *c.* Hernia of brain; monstrosity of the head or hydrocephalus.

Spine, Scapulas and Sacro-Iliac Joints

Class 1-A.—*a.* Normal spine and scapulas. *b.* Lateral curvature of the spine of 2 inches or less from the normal midline, if the mobility and weight-bearing power are good. *c.* Fracture of the coccyx. *d.* Prominent scapulas not interfering with wearing of uniform or military equipment. *e.* Pilonidal cyst or sinus (this usually presents itself in the region between the coccyx and anus), if unattended with disease of the bone as shown by x-ray examination. *f.* Normal sacro-iliac and lumbosacral joints. *g.* Complaint of disease of the sacro-iliac and lumbosacral joints which is unassociated with objective signs and symptoms at the first examination and which, on reexamination after a reasonable period of time, is again found negative.

Class 1-B.—*a.* Lateral deviation of the spine from the normal midline of more than 2 inches and less than 3 inches. *b.* Non-tuberculous diseases of the spine which are unassociated with such rigidity that the registrant has been incapacitated from following a useful vocation in civil life. *c.* Fracture of the spine or pelvic bones which has healed without marked defects and which has not interfered with following a useful vocation in civil life. *d.* Disease of the sacro-iliac and lumbosacral joints of a degree which disqualifies for general military service, if the registrant has followed a useful vocation in civil life.

Class 4.—Defects such as *a.* Tuberculosis, either active or healed, of any portion of the vertebral column. *b.* Osteoarthritis, partial or complete, of the spinal column if sufficient in degree to interfere with following a useful vocation in civil life. *c.* Healed fractures of the vertebrae or pelvic bones with associated disqualifying rigidity. *d.* Lateral deviation of the spine from the normal midline of more than 3 inches. Curvature

of the spine (kyphosis or lordosis) of a degree sufficient to interfere with the wearing of a uniform or military equipment, or which has prevented the registrant from following a useful vocation in civil life. *c.* Disease of the sacro-iliac and lumbosacral joints which is of a chronic type and is obviously associated with pain referred to the lower extremities, muscular spasm, postural deformities, and limitation of motion in the lumbar region of the spine, and if malingering is definitely excluded.

Use of X-Rays.—When examining physicians are in doubt concerning the cause and the extent of the diseases of the vertebrae, scapulas or sacro-iliac joints, an x-ray examination should be made.

Extremities

Class 1-A.—*a.* Normal upper and lower extremities with normal function. *b.* Old or recent fractures which have healed spontaneously with no resulting impairment of function. *c.* Paralysis of a muscle or group of muscles that does not interfere with function. *d.* Benign tumors of bone or defects due to their removal when the condition does not interfere with the function of the extremity or the joint involved. *e.* Recent injury of a bone or joint with or without fracture, or dislocation which, in the opinion of the examiners, is only temporarily incapacitating. (Registrants with these defects should be given a period of time not less than six weeks for recovery before the final examination is made.) *f.* Web fingers and toes, unless severe in degree. *g.* Absent left thumb. *h.* Loss of two fingers of either hand, except a combination of right index and middle finger. *i.* Loss of right index finger, provided right middle finger is present. *j.* Scars and deformities of moderate degree of the hand or hands which do not interfere with normal function. *k.* Stiff fingers of a degree not to interfere seriously with function. *l.* Pes planus unless accompanied by marked deformity, rigidity or weakness, or is of such degree as to have interfered with useful vocation in civil life. *m.* Hallux valgus unless severe. *n.* Clubfoot of slight degree if tarsal, metatarsal, and phalangeal joints are flexible and the condition permits the wearing of a military shoe and, in the opinion of the examiner, will not interfere with the performance of military duty. *o.* Slight claw toes not involving obliteration of the transverse arch and which do not interfere with the wearing of a military shoe. *p.* Hammer toe which is flexible and which does not interfere with the wearing of a military shoe. (Hammer toe usually involves the second digit and unless it is rigid is not a disqualifying defect.) *q.* Absence of one or two of the small toes of one or both feet if the function of the foot is good. *r.* Ingrowing toenails.

Class 1-B.—*a.* Loss of thumb of right hand. *b.* Loss of three fingers of either hand, including the right index finger. *c.* Web fingers or toes, if severe in degree. *d.* Ganglion and other benign tumors of the hand or fingers. *e.* Moderate deformities of one or both upper extremities which do not and have not interfered with function to a degree to prevent the registrant from following a useful vocation in civil life. *f.* Internal derangement of the knee joint if not severe enough to have prevented him from following a useful vocation in civil life. *g.* Abduction and pronation (knock-ankle) when this condition is not associated with rigidity of the tarsal joint or with deformity of the foot. (This defect is remediable with proper foot exercises and with correct shoes.) *h.* Loss of great toe. *i.* Loss of dorsal flexion of great toe. *j.* Hammer toe with rigidity. *k.* Other defects of the feet which disqualify for general military service but do not prevent the registrant from wearing a military shoe and which have not prevented him from following a useful vocation in civil life. *l.* Moderate deformities of one or both lower extremities which do not and have not interfered with function to a degree to prevent the registrant from following a useful vocation in civil life. *m.* Adherent scars of the skin and soft tissues of an extremity. *n.* Ununited fractures which do not interfere with good function. *o.* Benign tumors of bone or joint which do not interfere with function. *p.* Healed disease or injury of wrist or elbow with resulting limitation of motion. *q.* Other defects which, in the opinion of the examining physician, are disqualifying but remediable, but which have not prevented the registrant from following a useful vocation in civil life.

Class 4.—Defects such as *a.* Loss of both thumbs. *b.* Loss of more than three entire fingers of one hand. *c.* Chronic inflammatory disease of long duration of one or more of the large joints, with or without sinuses. *d.* Tuberculosis of a bone or joint. (The diagnosis should be based upon the presence of swelling, tenderness, muscular spasm, restriction of joint motion and the evidence of bone destruction shown by x-ray examination. *e.* Old ununited fractures which interfere with function or ununited fractures with deformity sufficient to interfere with function. *f.* Old unreduced dislocations which have interfered with the registrant following a useful vocation in civil life. *g.* Disease of any bone or joint healed with such resulting deformity or rigidity that the function is impaired to a degree that it will interfere with military service. *h.* Muscle paralysis or contraction which disturbs function to the degree of interference with military service. *i.* Adherent scars of skin or soft tissue to a degree which seriously interfere with function. *j.* Varicose veins, if severe in degree or if associated with edema or ulcer of the skin. *k.* Pes planus, if accompanied by marked deformity, rigidity, or weakness, or of such degree as to have interfered with useful vocation in civil life. *l.* Obliteration of the transverse arch associated with permanent flexion of the small toes (claw toes). *m.* Hallux valgus if severe and associated with marked exostosis or bunion, especially when there are signs of irritation above the joint. *n.* Clubfoot if marked in degree or which interferes with the wearing of a military shoe. *o.* Diseases of the bone or of the hip, knee, or ankle joint which seriously interfere with function and weight bearing power. *p.* Deformities due to fracture or other injury which seriously interfere with function and weight bearing power. *q.* Sciatica which is apparently intractable and disabling to the degree of interference with the function of walking and weight bearing power. *r.* Amputations of extremities in excess of those already cited.

General Considerations.—It is important that registrants with defects of the feet which are not remediable by training and which prevent the inducted men from taking proper training should not be accepted for general military service. It is quite as important that defects of the feet which are not disabling should not be considered disqualifying for general military service.

Neck

Class 1-A.—*a.* Normal neck. *b.* Nonspastic contraction of the muscles of the neck which is not of great degree and will not prevent the wearing of a uniform or military equipment. *c.* Simple goiter or benign thyroid tumors unassociated with toxic or pressure symptoms, provided the enlargement of the thyroid will not interfere with the wearing of a uniform or military equipment. *d.* Enlarged lymph glands of the neck which are not a manifestation of systemic disease and which apparently do not interfere with the general health and which are not large enough to interfere with the wearing of a uniform or military equipment.

Class 4.—*a.* Exophthalmic goiter. *b.* Thyroid enlargement from any cause associated with toxic symptoms. *c.* Enlargement of the lymph glands of the neck associated with leukemia and Hodgkin's disease. *d.* Lymphosarcoma. *e.* Tuberculous glands. *f.* Nonspastic contraction of the muscles of the neck or cicatricial scarring which is disfiguring and unsightly or interferes with wearing a uniform or military equipment. *g.* Spastic contraction of the muscles of the neck. *h.* Simple goiter unassociated with toxic or pressure symptoms, enlarged lymph glands of the neck, benign tumors and cysts of the neck, large benign tumors of the parotid gland, if the enlargement is of such degree as to interfere with wearing a uniform or military equipment.

Lungs and Chest Wall

Class 1-A.—*a.* Normal respiratory system and chest wall. *b.* Acute bronchitis, provided acceptance is temporarily deferred until a final examination shows recovery without disqualifying sequelae. *c.* Scars of operation for empyema which have been healed for one year or longer, when the function of the lung is good. *d.* (1) Arrested pulmonary tuberculosis consisting of lesions appearing in x-ray examination as small apical scars,

small calcified nodules or localized fibrous strands, in no case exceeding minimal extent as defined in the classification of the National Tuberculosis Association, and when, in addition, in the opinion of the examining physician, this lesion is not likely to be reactivated under conditions of military service. (2) Minimal pulmonary lesions are defined as slight lesions without demonstrable excavation confined to a small part of one or both lungs. The total extent of the lesions, regardless of distribution, will not exceed the equivalent of the volume of lung tissue which lies above the second chondrosternal junction and the spine of the fourth or body of the fifth thoracic vertebra on one side. *e. Fracture of the rib or ribs, provided acceptance of registrant is temporarily deferred until a final examination shows recovery with or without deformity, and provided the residual deformity, if any, does not interfere with respiratory movements.* *f. Benign tumors of the breast or of the chest wall, provided the enlargement does not interfere with the wearing of a uniform or military equipment.* *g. Small palpable lymph glands of the axilla which apparently do not interfere with the general health.*

Class 1-B.—*a. Deformity of clavicle, ribs, or scapula of a degree disqualifying for general military service but which has not prevented the registrant from successfully following a useful vocation in civil life.* *b. Chronic bronchitis, bronchiectasis, or chronic asthma which is mild and which has not prevented the registrant from successfully following a useful vocation in civil life.*

Class 4.—Disqualifying defects such as *a. Tuberculosis of lungs or tracheobronchial lymph nodes, except as defined for Class 1-A.* *b. Fibrinous or serofibrinous tuberculous pleuritis, and pleurisy, with effusion of unknown origin. (As pleurisy, with or without effusion, is a very frequent manifestation of early tuberculosis, examining physicians should examine with the greatest care registrants who have apparently recovered from pleurisy.)* *c. Empyema, or unhealed sinuses of the chest wall following operation for empyema.* *d. Chronic bronchitis with emphysema except as stated for Class 1-B.* *e. Chronic asthma associated with chronic bronchitis and emphysema, except as stated for Class 1-B.* *f. Abscess of the lung.* *g. Bronchiectasis, if moderate or severe.* *h. Actinomycosis.* *i. Tuberculosis of the ribs and other parts of the chest wall.* *j. Tumor of the breast or of the chest wall of such size and location as to interfere with the wearing of the uniform or military equipment.* *k. Tumor of the lung, pleura, or mediastinum.* *l. Spontaneous pneumothorax.*

General Considerations.—*a. The chest examination will include the usual methods of physical diagnosis supplemented, whenever indicated, by radiographic and laboratory studies.* *b. Examining physicians should be extremely careful to reject registrants with pulmonary tuberculosis, except as defined for Class 1-A for all military service; and to accept for military service registrants who allege tuberculosis as a ground for exemption or discharge on the basis of insufficient or incorrectly interpreted signs and symptoms.* *c. Men who desire to serve their country may conceal, from patriotic motives, symptoms of tuberculosis which they know or suspect to exist. Some tuberculous individuals will seek enlistment with a view to obtaining treatment and a pension. Some soldiers may allege symptoms of tuberculosis with a view to securing discharge. Some registrants may be expected to claim the existence of tuberculosis as a ground for exemption and fortify their claims by certificates of physicians and by roentgenograms. Such certificates and roentgenograms will not be accepted, but examining physicians will satisfy themselves as to the physical qualifications of registrants by their personal examinations. There will be cases in which pulmonary tuberculosis will have been previously diagnosed on the ground of subjective symptoms and of physical signs which are without any pathologic significance. It is necessary, therefore, that conclusions of examining physicians will be based only on their own examinations. Statements of the registrant as to symptoms will not be accepted as indication of the existence of tuberculosis unless supported by objective evidence.* *d. The attention of examining physicians is particularly invited to the necessity of exercising great conservatism in their interpretation of physical signs over*

the apexes. Interpretation of such signs as indicating active tuberculosis would in many cases do the government great injustice, leading to the exclusion of men who are fit for service. *e. The following signs may arouse suspicion, but unless x-ray and other studies reveal definite evidence of disease they will be disregarded. (1) Slightly harsh breathing, slightly prolonged expiration over the right apex above the clavicle anteriorly and to the third dorsal vertebra posteriorly; the same signs at the extreme apex, left side. (2) Same signs at second interspace right anteriorly near sternum (proximity of right main bronchus). (3) Increased vocal resonance, slightly harsh breathing immediately below center of left clavicle. (4) Fine crepitations over sternum heard when stethoscope touches the edges of that bone. (5) Clicks heard during strong respiration or after cough in the vicinity of the sternocostal articulations. (6) The so-called rales at the apex during the first inspiration which follows a deeper breath than usual or a cough. (7) Sounds resembling rales at base of lung (marginal sounds), especially marked in right axilla, limited to inspiration. (8) Similar sounds heard at apex of heart on cough (lingula). (9) Slightly prolonged expiration at left base posteriorly. (10) Very slight harshness of respiratory sounds with prolonged expiration in the lower paravertebral regions of both lungs posteriorly.*

Heart, Blood Vessels and Circulation

History.—Questions may be asked during the course of the examination concerning past history of rheumatic fever, syphilis and reaction of physical effort which may be helpful in the interpretation of the observations, but reliance should not be placed on the history alone.

Procedure.—The procedure following should govern in the physical examination of the heart. Only those observations need be recorded which are indicative of disease or anatomic defect (examples of conditions which are usually not indicative of disease are extrasystoles and functional pulmonary systolic murmurs). For the information of the examiners it is suggested that reference be made to the publication of the American Heart Association entitled "The Nomenclature and Criteria for the Diagnosis of Diseases of the Heart." *a. Location and determination of character of apex impulse.* *b. Auscultation of the heart sounds over apex, lower sternum, and second and third interspaces to right and left of sternum, noting accentuation of sounds and murmurs, and rate and rhythm, and comparing apex observations with the radial pulse.* *c. Inspection of root of neck and upper thorax and percussion of first interspace on each side of manubrium for evidence of aneurysm.* *d. Count of radial pulse, observation of its rhythm, and palpation of radial arteries for unusual thickening or high tension.* *e. The blood pressure will be determined only in those cases in which it appears indicated.* *f. Exercise test (stepping twelve times briskly onto a common chair) will be used in selected cases to bring out significant heart murmurs, but this test in itself is not to be considered a reliable estimate of the functional capacity of the heart. Care will be taken that registrants with heart lesions are not placed in jeopardy by overexercise.* *g. If there is doubt as to the presence of cardiovascular disease the registrant should return for detailed reexamination.*

Class 1-A.—*a. Normal heart. (A heart will be considered normal when the apex impulse is within the left midclavicular line and not below the fifth interspace; when sounds are normal and there are no thrills or important murmurs; when there is no abnormal pulsation or dullness above the base of the heart; when pulse rate is normal and regular and there is no unusual thickening of the arteries or evidence of high blood pressure.)* *b. A pulse rate of 100 or over which is not persistent. (A pulse rate of 100 or over may be temporary and due to excitement or to recent infection, such as pneumonia or local infections about the nose, mouth and throat, or may be induced by drugs.)* *c. A pulse rate of 50 or under which is proved to be the natural pulse rate of the registrant or to be temporary or due to the use of drugs.* *d. Sinus irregularity. (This consists in a quickening of the pulse rate during inspiration and a slowing during expiration and is best recognized with the registrant recumbent and breathing deeply.)* *e. Elevation of blood pressure from excitement, proved to be temporary.* *f. Neurocirculatory asthenia, if mild in degree.*

Class 1-B.—There are no cardiovascular criteria to warrant initial selection for class 1-B.

Class 4.—*a.* Circulatory failure evidenced by definite symptoms such as a combination of breathlessness, cyanosis and edema. *b.* Hypertrophy and dilatation of the heart evidenced by displacement of the apex impulse to the left of the mid-clavicular line or below the sixth rib, and of a heaving or diffuse character. *c.* A persistent heart rate of 100 or over when this is proved to be persistent in the recumbent posture and on observation and reexamination over a sufficient period of time. *d.* Paroxysmal tachycardia. *e.* Heart block. *f.* Any serious disturbance of rhythm, such as auricular fibrillation. *g.* Valvular disease. *h.* Congenital heart disease. *i.* Persistent blood pressure at rest above 150 mm. systolic or above 90 diastolic, unless in the opinion of the medical examiner the increased blood pressure is due to psychic reaction and not secondary to renal or other systemic disease. *j.* Thrombophlebitis of one or more extremities if there is a persistence of the thrombus or any evidence of obstruction of circulation in the involved vein or veins. *k.* Other abnormalities of the peripheral vascular system, including large varicose veins, Raynaud's disease, Buerger's disease (thrombo-angiitis obliterans), erythromelalgia, and arteriosclerosis of the leg vessels. In doubtful cases special tests should be employed. *l.* Aneurysm of any vessel. *m.* Pericarditis. *n.* Acute endocarditis. *o.* Angina pectoris clearly due to coronary insufficiency. *p.* Coronary thrombosis. *q.* Neurocirculatory asthenia (effort syndrome), unless mild.

Electrocardiogram.—The electrocardiogram is of great assistance in determining the nature of certain cardiac abnormalities, the most important of which are the various arrhythmias, defects in conduction, and diseases of the coronary arteries. The electrocardiograph may be utilized in cases in which such diagnostic aid is especially indicated but will not be employed as a routine measure.

X-Ray Examination.—In doubtful cases fluoroscopy is advised to determine the size and shape of the heart and great vessels. Such films as may be taken for the study of the lungs of the registrants should also be viewed for cardiovascular defects.

General Considerations.—*a.* It is incumbent on examining physicians (1) To accept for service men with accidental functional murmurs or other conditions which do not indicate disease and do not impair the individual's ability to undergo severe bodily exertion. (2) To exclude from active service in the Army any registrant affected with disease of the heart or blood vessels which impairs his ability to undergo severe bodily exertion. Although many men with compensated valvular heart disease are able to undergo severe bodily exertion, the question of aggravation in service, especially by activation of rheumatic carditis, is likely to arise and incidentally to create a pension problem. Therefore all registrants with valvular heart disease are to be regarded as unfit for service and will be placed in class 4. *b.* Men who desire to serve their country may from patriotic motives endeavor to conceal a known valvular lesion which has given no symptoms. On the other hand, men drafted for service may allege or feign symptoms to obtain exemption. Registrants may be expected to present physicians' certificates to substantiate the existence of valvular disease. Many of these may be given in good faith because of inadequate knowledge of the significance of certain frequent murmurs. Such certificates will not be accepted, but examining physicians will satisfy themselves by their personal examinations as to the physical qualifications of registrants. *c.* It is necessary, therefore, that the conclusions of the examining physician in doubtful cases will be based on objective evidence in the widest sense, including both physical signs, cardiac rhythm, measurement of blood pressure, and the observed effect of effort. Nevertheless, in the presence of questionable signs or symptoms, the history, especially of past rheumatic fever may be a factor in the final decision. No statement, however, will be accepted as proof of the existence of a cardiovascular defect unless supported by objective evidence. *d.* Since it is the duty of examining physicians to protect the interests of the government by preventing men from entering the service whose circulatory systems may be expected to break down under strain, and equally by pre-

venting the exemption or discharge of fit subjects because of unimportant deviations from the normal, it will be necessary for them to exercise care in the interpretation of their observations and to bear in mind constantly the murmurs and other departures from the supposed normal which may occur in perfectly healthy hearts.

Abdominal Organs and Wall

Class 1-A.—*a.* Normal abdominal organs and abdominal wall. *b.* Abdominal scars due to surgical operation or accident which show no hernial bulging. *c.* Scar pain when found not associated with any disturbance of function of abdominal wall or contained viscera, unless malingering is definitely excluded. *d.* Achylia gastrica, unless associated with a disqualifying disease. *e.* Complaint of weak stomach, indigestion, dyspepsia, constipation, belching, vomiting, and various other types and degrees of abdominal discomfort which are proved by examination not to be associated with organic disease, by the absence of the usual objective symptoms and signs and by such laboratory tests as may be employed, provided psychiatric examination reveals no disqualification. *f.* Blood in stools if proved to be due to slight defects, such as fissures of the anus, small hemorrhoids or superficial small ulcers of the rectum. *g.* Mild enlargement of the liver unassociated with other objective evidence of disease of the liver or other organs. *h.* Splenic enlargement of mild degree unassociated with evidence of other disqualifying disease. *i.* Small benign tumors of the abdominal wall. *j.* Intestinal parasites or their eggs in the stools. *k.* Internal and external hemorrhoids if mild in degree.

Class 1-B.—Unless the degree of disability is obviously disqualifying, *a.* Hernia-inguinal, femoral, umbilical and postoperative. *b.* Large benign tumors of the abdominal wall. *c.* Internal hemorrhoids moderately severe, if remediable.

Class 4.—Defects such as *a.* Inoperable hernia. *b.* Hydatids of the liver. *c.* Ulcer of the stomach or duodenum, if diagnosis is confirmed by the usual laboratory procedures. *d.* Obstruction of the bowel due to organic disease. *e.* Irremediable sinuses of the abdominal wall communicating with the hollow viscera. *f.* Irremediable stricture of the rectum. *g.* Multiple fistulas of the anus. *h.* Schistosomiasis. *i.* Enlargement of the spleen associated with leukemia, Hodgkin's disease or splenic anemia. *j.* Great enlargement of the spleen from any cause. *k.* Large internal and external hemorrhoids associated with prolapse of the rectum. *l.* Paralysis of the sphincter associated with incontinence of feces.

General Considerations.—*a.* When necessary to confirm a diagnosis, examining physicians should, when possible avail themselves of fluoroscopy and roentgenography when examining registrants. *b.* When examining physicians are able to command hospital facilities and the necessary diagnostic apparatus, they should, within their discretion, use test meals and chemical and microscopic examination of the stomach contents and stools. *c.* Examining physicians should make use of digital rectal examination of defects referable to that region, and, when necessary, proctoscopy should also be utilized. *d.* Registrants who are found to have parasites or their eggs in stools should have this condition indicated on report of examination. *e.* Moderate impulse produced by cough at the inguinal, femoral, or umbilical rings, or at the site of a scar is not necessarily indicative of hernia.

Genito-Urinary Organs and Venereal Diseases

Class 1-A.—*a.* Gonorrhea, acute or chronic. *b.* Syphilis with remediable manifestations except cerebrospinal, cardiovascular or visceral syphilis. *c.* Chancroids and the resulting infections of the lymph glands of the groin. *d.* Bed wetting, if mild in degree. *e.* Albuminuria with or without casts which is proved by observation and repeated examination to be temporary in character. *f.* Absence of one testicle due to removal or atrophy. *g.* Undescended testicle which lies within the abdominal cavity. *h.* Acute cystitis which has proved to be of a temporary character by observation and repeated examination over a period not to exceed six weeks. *i.* Phimosis with or without adhesions of the mucous surfaces, if remediable. *j.* Benign warts and other benign growths of the glans penis and of the prepuce. *k.* Amputation of the penis if a sufficient amount of the organ remains so as

not to interfere with the function of micturition. (Care should be taken to examine registrants fully for possible recurrence of a disqualifying disease for which the amputation was made.)
l. Varicocele of moderate size. *m.* Hydrocele of moderate size.

Class 1-B.—*a.* Stricture of the urethra, unless severe and irremediable. *b.* Benign tumor of the testicles. *c.* Cystitis, sub-acute or chronic, if deemed remediable. *d.* Varicocele if large. *e.* Hydrocele, if large and considered irremediable to a degree which would qualify for class 1-A but would permit limited service. *f.* Floating kidney. (By floating kidney is meant one which is freely movable.) *g.* Undescended testis which lies within the inguinal canal. *h.* Removal of one kidney, the remaining one being healthy. *i.* Bed wetting if more than mild in degree.

Class 4.—*a.* Chronic nephritis. This should be evidenced by the presence in the urine of albumin and casts, with or without blood, over a period of time sufficient to prove the persistence of the urinary condition. Examining physicians should require registrants to void the urine during the period of the examination and in their presence. When albumin and casts are found in the urine, the registrants should be reexamined not less than twice a day on two or more separate days. If the urine shows albumin and casts with or without blood, and this condition of the urine is associated with enlargement of the heart, high blood pressure and other evidences of cardiovascular disease, the diagnosis of chronic nephritis may be made immediately. If the presence in the urine of albumin and of casts with or without blood is proved to be inconstant, and if the condition is unassociated with the cardiovascular condition mentioned, decision should lie within the judgment and discretion of the examining physicians. *b.* Irremediable stricture of the urethra, unless of such slight degree as to be of no pathologic significance. *c.* Urinary fistula or incontinence. *d.* Gonorrheal arthritis which is of itself disqualifying. *e.* Surgical kidney with or without renal calculus. *f.* Irremediable pyelitis. *g.* Hydro-nephrosis or pyonephrosis. *h.* Tumors of the kidney or bladder. *i.* Acute nephritis if moderately severe and persistent after one month's observation. *j.* Chronic cystitis associated with calculi or with retention of urine caused by stricture of the urethra or by disease of the central nervous system. *k.* Amputation of the penis if the resulting stump is insufficient to permit of normal function of micturition. *l.* Hermaphroditism. *m.* Hypertrophy of the prostate gland of sufficient degree to cause retention of the urine. *n.* Epispadias or hypospadias when urine cannot be voided in such a manner as to avoid soiling of clothing or surroundings, or when accompanied by evidence of chronic infection of the genito-urinary tract. *o.* Cardiovascular, cerebrospinal and visceral syphilis.

General Considerations.—*a.* When it is deemed necessary, examining physician should employ x-ray facilities to verify diagnosis of defects of the genito-urinary organs. *b.* Complications and sequelae of gonorrhea will be regarded by examiners as acceptable or as disqualifying, depending on the degree of seriousness in individual cases, and registrants will be appropriately classified according to the best judgment of the medical examiners.

Endocrine and Metabolic Disorders

Class 1-A.—*a.* Goiter (enlargement of thyroid gland, diffuse or nodular) if unassociated with toxic or pressure symptoms, provided the enlargement of the thyroid will not interfere with the wearing of a uniform or military equipment. *b.* Froelich's syndrome, if very mild in degree. *c.* Hypothyroidism without myxedema, if not severe or resistant to cure. *d.* Acromegaly if not severe or associated with symptoms other than the bony changes. *e.* Pellagra, beriberi, scurvy and other nutritional deficiencies, if remediable by correction of diet and not severe. *f.* Glycosuria, if transient or renal in type, provided acceptance is deferred until the possible existence of diabetes mellitus is excluded.

Class 1-B.—Froelich's syndrome, if moderate in degree.

Class 4.—*a.* Toxic goiter or thyrotoxicosis. (It should be remembered that malingerers may by use of thyroid medication produce many of the symptoms of thyrotoxicosis.) *b.* Goiter with definite pressure symptoms or so large in size as to interfere with wearing a uniform or military equipment. *c.* Cretin-

ism with imbecility or dwarfism. *d.* Myxedema (with clinical manifestations, and diagnosis not based only on low basal metabolic rate). *e.* Gigantism or acromegaly if markedly disfiguring or if associated with other symptoms of severe pituitary dysfunction. *f.* Froelich's syndrome, if severe. *g.* Hyperparathyroidism and hypoparathyroidism, unless mild in degree. *h.* Addison's disease. *i.* Diabetes mellitus and diabetes insipidus. If sugar is found in the urine, further specimens should be voided in the presence of the physician or authorized assistant, and on more than one occasion to avoid the substitution of diabetic urine or the voiding of diabetic or dextrose containing urine previously introduced into the bladder by catheter. In doubtful cases the blood sugar should be determined. Before diabetes insipidus is diagnosed, malingering (by drinking a large quantity of water) should be excluded. *j.* Avitaminoses (including sprue, beriberi, pellagra and scurvy) which are severe or not readily remediable, or in which permanent pathologic changes have been established. *k.* Gout. *l.* Simmond's disease. *m.* Cushing's syndrome.

Diseases of the Blood and Blood-Forming Tissues

Class 1-A.—*a.* Secondary anemia, due to hemorrhoids or any other remediable cause. *b.* Purpura if symptomatic of a remediable condition. *c.* Sick cell anemia, if not severe. *d.* Malaria, acute or chronic, unless severe and irremediable.

Class 1-B.—Primary pernicious anemia in the absence of posterolateral sclerosis, if responsive to treatment and not severe.

Class 4.—*a.* Hemophilia. *b.* Thrombocytopenic purpura. *c.* Primary pernicious anemia if severe, not responsive to treatment or with neurologic complications. *d.* Aplastic anemia. *e.* Hemolytic ictero-anemia (hemolytic jaundice). *f.* Splenic anemia. *g.* Polycythemia vera. *h.* Leukemia, acute or chronic, of any type.

Mental and Nervous Disorders

Class 1-A.—*a.* A normal nervous system. *b.* Registrants who appear to have normal understanding, whose speech can be understood, who have no definite signs of organic disease of the brain, spinal cord or peripheral nerves, and who are otherwise mentally and physically fit. *c.* Muscular tremors of moderate degree, unless malingering is definitely excluded.

Class 1-B.—*a.* Stuttering and stammering of a degree disqualifying for general military service but which has not prevented registrants from successfully following a useful vocation in civil life. *b.* Tremors of such marked degree that they disqualify for general military service but have not prevented the registrants from following a useful vocation in civil life.

Class 4.—Any serious mental or neurologic disorder such as *a.* Insanity. *b.* Epilepsy. *c.* Postencephalitic syndrome. *d.* Imbecility. *e.* Drug addiction, including the habitual use of opium and its derivatives and cocaine. *f.* Chronic alcoholism. *g.* Stammering to such a degree that the registrant is unable to express himself clearly or to repeat commands. *h.* Psychoneuroses and constitutional psychopathic states, provided the diagnosis is clearly established and in the opinion of the medical examiner precludes the successful performance of military duty. *i.* Chronic essential chorea. *j.* Syphilis of central nervous system. *k.* Post-traumatic cerebral syndrome. *l.* Multiple sclerosis. *m.* Paraplegia or hemiplegia. *n.* Syringomyelia. *o.* Muscular atrophies and dystrophies which are obviously disqualifying. *p.* Hysterical paralysis. *q.* Neuritis or neuralgia which is not temporary in character and which has progressed to such a degree as to prevent the registrants from following a useful vocation in civil life. *r.* Brain tumors. *s.* Cerebral arteriosclerosis. *t.* Sexual perversion.

Diagnostic Criteria.—In arriving at decisions concerning nervous or mental defects, the following criteria may be of assistance: *a.* Insanity.—All registrants should be considered insane who are committed, or who have been committed, to a licensed public institution for the care of the insane. The examining physicians may require proof in the form of verified records of commitment by the proper state authorities to verify the statements of the registrants. (1) *Dementia Praecox.*—Look for indifference, apathy, withdrawal from environment, ideas of reference and persecution, feelings of the mind being tampered with, or thought being controlled by hypnotic, spiritualistic or

other mysterious agencies, hallucinations of hearing, bodily hallucinations, frequently of electrical or sexual character; meaningless smiles; in general, inappropriate emotional reactions and lack of connectedness in conversation. There may be sudden emotional or motor outbursts. The history of family life and of school, vocational and personal career will usually show erratic and more or less irrational conduct. (2) *Manic-Depressive Insanity*.—Look for mild depression, with or without feeling of inadequacy, or mild manic state with exhilaration, talkativeness and overactivity. (3) *Paresis*.—The diagnosis of paresis may be made when at the examination of the registrant a majority of the following signs and symptoms are demonstrated: Argyll Robertson pupil, facial tremor, speech defect in test phrases and in the slurring and distortion of words in conversation; writing defects, consisting of omissions and the distortion of words; apathetic or depressed or euphoric mood. These registrants may show memory loss or discrepancies in relating facts of life; the knee jerks may be plus, minus or normal. *b. Epilepsy*.—The registrant will not be considered epileptic unless the claim is substantiated by characteristic scars on the tongue, face or head or, if the examining physician is in doubt, by properly certified proof. *c. Imbecility*.—A registrant will be declared an imbecile who has been so defective in mind from birth or early age as to be incapable of earning a livelihood but at the same time is able to guard himself against common physical danger. *d. Chronic Alcoholism*.—(1) A registrant will be declared a sufferer from chronic alcoholism when he presents a majority of the following symptoms and signs: suffused eyes; prominent superficial blood vessels of nose and cheek; flabby, bloated face; red or pale purplish discoloration of mucous membrane of the pharynx and soft palate; muscular tremor of the protruded tongue and extended fingers; tremulous handwriting. (2) The history of evidence presented that the registrant has been frequently and grossly intoxicated is not of itself sufficient proof for the diagnosis of chronic alcoholism. *e. Tabes*.—The diagnosis of this disease should be made when, at the examination of the registrant, several of the following signs and symptoms are present: Argyll Robertson pupil; absent knee jerks; positive Romberg, ataxic gait (especially when the eyes are closed); hypotonia, and anesthetic areas of the skin. The history of tabes is usually that of slow progression, of failing sexual power, and pains in the legs or back which are often described as rheumatism. *f. Cerebrospinal Syphilis*.—The prominent diagnostic signs and symptoms are headaches, varying deep and superficial reflexes, pupillary changes, ptosis, ocular palsies, facial weakness; the mental state may be normal, dull or apathetic. Comparative motor weakness may involve one side of the body or one extremity. *g. Multiple Sclerosis*.—The diagnosis of this disease rests on the following signs and symptoms: intention tremor, nystagmus, absent abdominal reflexes, increased tendon reflexes, and scanning speech; in cases of this kind the history obtained is not characteristic, but sometimes there may be a history of urinary disturbances. *h. Paraplegia*.—The diagnosis of paraplegia from whatever cause will rest on weakness of the lower extremities, associated with loss of or increased knee jerks, Babinski reflex or disturbance of the sphincters of the rectum and bladder, with or without girdle sensations. Sensory disturbance of the skin may or may not be present. Muscle sensibility may be diminished. *i. Syringomyelia*.—Syringomyelia is usually evidenced by more or less loss of power and atrophy of groups of muscles of one or more extremities; disturbance of the sensations of the skin, more especially in the form of analgesias, and diminution of the temperature sense; if in the upper dorsal cord, often associated with stooped shoulder posture; if in the lower dorsal, with weakness in one or both lower extremities. *j. Muscular Atrophies and Dystrophies*.—The signs and symptoms of muscular atrophies and dystrophies are atrophies of the small muscles of the hand and of the muscle groups of the shoulder; fibrillary twitchings. The history of these defects rarely furnishes reliable data, although it will usually be found that the registrant has shown evidences of awkwardness. There is never a history of pain in the affected muscles. *k. Multiple Neuritis*.—The chief manifestations are more or less pain in the course of the affected nerves, with tenderness over the trunks of the nerves and of the muscles supplied by them; lessened muscular power of varying degrees;

more or less atrophy of muscles, with or without contraction, and evidences of trophic changes of the skin. The reflexes, deep and superficial, may be diminished or absent; the sphincters are not involved.

Sequelae of Organic Neurologic Disease.—Certain after-effects of organic nervous disease need not be causes for rejection, provided *a.* The disease is no longer active and is not likely to recur. *b.* The effect left by it does not prevent a satisfactory fulfillment of military duties. Examples of such conditions are paralysis of a few unimportant muscles following poliomyelitis, slight unilateral hypertonicity as a result of an infantile hemiplegia in a man now robust, and various traumatic conditions.

Purposely Caused Physical Defects

Report of Apparently Purposely Caused Defects.—Whenever it shall appear to an examining physician that a registrant is suffering from self-inflicted or purposely caused physical defects which, under the standards of physical examination prescribed herein, would render him disqualified for military service of any kind, a full statement of the facts and of the condition of the registrant and of the examining physician's recommendation will be prepared and submitted to the Director of Selective Service or other designated authority for a waiver of the physical defects, if recommended, so that the registrant may be compelled to render military service.

Notes on Malingering

Types of Malingerers.—Maleringers may be divided into three general groups: *a.* Real malingerers with nothing the matter with them, who injure themselves, or make allegations respecting diseases or such condition as drug taking, or who simulate disease with full consciousness and responsibility—all for the purpose of evading military service. Many of these will have been coached. *b.* The psychoneurotic, who are natural complainers and try to get out of every disagreeable thing in life; perhaps only partially conscious of the nature of the seriousness of what they do and only partly responsible. In many the motives are not persistent and many can be made into good soldiers. *c.* Confirmed psychoneurotic individuals with long history of nervous breakdowns and illnesses who behave like group *a* above but more persistently and from whom not much can be expected in the way of reconstruction.

Feigned Medical Diseases.—*a.* The detection and management of malingerers simulating medical diseases depend on the absence of positive signs in an individual who presents the general characteristics of the malingerer. There is especial need for the physical examination to be thorough in this group. Some of the cardiac cases at first regarded as malingering may later be found to be mitral stenosis or bacterial endocarditis. Similarly, proper tests may show the existence of peptic ulcers in those suspected of feigning digestive abnormalities. The estimation of the reality of rheumatic pains is always a difficult matter. *b.* Tachycardia and thyrotoxicosis may be temporarily induced by ingestion of drugs, such as thyroid extract. Egg albumin or sugar may be added to urine. Undiluted canned milk may be made to simulate the urethral discharge. Cantharides may be taken to cause albuminuria. Digitalis and strophanthus may be taken to cause abnormal heart action. The skin may be irritated by various substances. Cathartics may be taken to bring about purging or to simulate a chronic diarrhea. An appearance of hemoptysis may be produced by adding blood, either human or that of animals, to the sputum. Sometimes merely coloring matter is added. Those who can vomit voluntarily what they swallow use the same means to create the appearance of hematemesis. Similarly, coloring matter may be added to the stools. Mechanical and chemical irritants are made use of to cause inflammation about practically all the body orifices. Jaundice may be simulated by taking picric acid. Crutches, spectacles, trusses and strappings are made use of to create the appearance of disability. Artificial jaundice is recognized by demonstration of picric acid in the urine.

Feigned Surgical Conditions.—Under this are included old scars and injuries of the bones, fractures and orthopedic conditions. Men may have teeth extracted in an effort to evade military service. Others may shoot or cut off their fingers or toes, practically always on the right side, to disqualify

themselves for service. Some may put their hands under cars for this purpose. Retention of urine may be simulated. Substances may be injected under the skin to create abscesses. Crutches, braces, strappings or trusses may be used to give the appearance of disability. Wounds are rarely self inflicted when witnesses are present; consequently it is almost impossible to be certain of malingering in some cases.

Nervous and Mental Feigned Illness.—*a. Insanity.*—Rarely feigned by registrants and then of an extremely silly, foolish type. In case of doubt, hospital observation is necessary, with verified past records. Mental defects are frequently feigned, especially by illiterates. Organic diseases of the central nervous system cannot be simulated. *b. Pain and Hyperesthesia.*—The most frequent of all complaints. History inconsistent, ordinary traces of suffering absent. Absence of other symptoms usually accompanies types of pain complained of. Absence of objective evidence of localized pains. Note behavior when the registrant believes himself unobserved. *c. Anesthesia.*—Complaint of anesthesia itself creates a suspicion of malingering, as most patients with anesthesia are ignorant of it. *d. Epilepsy.*—Men who have sustained head injury are very apt to claim fits. These complaints may be in reference to grand mal or petit mal. Petit mal attacks are spoken of as fainting attacks. In grand mal attacks there is loss of pupil response to light, knee jerks are lost, and the Babinski reflex may be present. *e. Hysteria.*—Not feigned in itself, but its existence creates confusion as to malingering. The question to be decided is whether the registrant is too seriously affected with the neurosis to be useful as a soldier. *f. Stiff Back.*—Stiff back is a frequent symptom of hysteria in mobilization among selected men. In cases of this kind, organic diseases of the vertebrae can and should be excluded, if necessary, by x-ray examination.

Bed Wetting.—Enuresis, either real or simulated, may be a frequent complaint among registrants for military service, but it is not a cause for unconditional rejection. Bed wetters may be placed in class 1-A or 1-B depending on the apparent significance or severity of the disorder.

General Considerations.—*a.* The surest means of detecting malingering is a thorough understanding by the examining physician of the types of people who actually do it, and the way they behave. It is only in the feigned diseases of the eye and ear that special tests are required. Observation in hospital is necessary in difficult cases. The vast bulk of malingerers are those who exaggerate some actual defect, and the problem for the examining physician is to decide whether the defect complained of is sufficient cause for rejection for service. Persons of intelligence and education have more difficulty in deceiving, as they are bound to express themselves freely. If they are reticent in these matters they arouse suspicion by their reticence. Those who talk freely may be counted on to say things at variance with the existence of the disease of which they complain. *b.* Whenever it shall appear to an examining physician that a registrant is endeavoring to escape service by malingering, if otherwise mentally and physically fit, he will be accepted. A full statement of the facts will be prepared and forwarded to the Director of Selective Service.

NEW YORK MEETING ON MILITARY MEDICINE

The Second District Branch of the Medical Society of the State of New York will hold its thirty-fourth annual meeting at Mitchel Field, Garden City, November 13. The theme of the meeting will be Military Medicine. Among the speakers will be:

Dr. Samuel J. Kopetzky, New York, Plans of the Medical Profession for National Preparedness and Mobilization.
Col. Julius Blank, medical corps, U. S. Army, Second Corps Area, General Principles of Medicomilitary Care and Evacuation.

Dr. Clarence R. Straatsma, New York, Plastic Surgery in Connection with General Medical Work.

Lieut. Col. Martin F. DuFrenne, medical corps, U. S. Army, Fort Jay, Governors Island, Treatment of Head Injuries.

Col. Floyd Kramer, medical corps, U. S. Army, Fort Totten, Flushing, Hospitalization in the Zone of the Interior and in the Theater of Operations.
Dr. Virgil H. Moon, Philadelphia, Practical Phases of the Early Recognition and Management of Shock.
Lieut. Col. Charles L. Maxwell, medical corps, U. S. Army, Mitchel Field, Aviation Medicine.

Addresses will be given by Col. Douglas B. Netherwood, air corps, commanding officer, Mitchel Field, and Dr. James M. Flynn, Rochester, president of the state medical society. A program has also been planned for the local woman's auxiliaries.

Organization Section

OFFICIAL NOTES

ADDRESSES BY OFFICIAL STAFF

DR. PAUL C. BARTON:

Nov. 26—Chicago Woman's Aid, Chicago.

DR. W. W. BAUER:

Nov. 6—Yale University School of Medicine, New Haven, Conn.

Nov. 8—New England Superintendents Association, Boston.

Nov. 8—Harvard School of Public Health, Boston.

Nov. 12—Englewood Evening School, Chicago.

Nov. 13—Cleveland Health Museum, Cleveland.

Nov. 18—Boone County Medical Society, Woman's Auxiliary, Jefferson City, Mo.

Nov. 18—Boone County Medical Society, Columbia, Mo.

Nov. 19-20—Stephens College, Columbia, Mo.

Nov. 26—Irving Park Branch, Chicago Medical Society, Woman's Auxiliary, Chicago.

Dec. 6-7—National Education Association, Yearbook Committee, Pittsburgh.

DR. MORRIS FISHBEIN:

Nov. 6—Woman's Auxiliary to North Side Branch Chicago Medical Society, A. M. A. Headquarters.

Nov. 8—Radio Broadcast, National Foundation for Infantile Paralysis, Inc., New York.

Nov. 12—Englewood Branch Chicago Medical Society, Chicago.

Nov. 14—American Conference on Industrial Health, Chicago.

Nov. 24—Joliet Sunday Evening Club, Joliet, Ill.

Dec. 4—Ingham County Tuberculosis Society and Ingham County Medical Society, Lansing, Mich.

Dec. 4—Town Hall, Lansing, Mich.

DR. FRANK H. LAHEY:

Nov. 1—Duke University School of Medicine, Durham, N. C.

Nov. 7—House Officers Association, Boston City Hospital, Boston.

Nov. 7—Brockton Medical Society, Toll House, Whitman, Mass.

Nov. 14—Geneva Academy of Medicine, Geneva, N. Y.

Nov. 18—Massachusetts Hospital Association, Parker House, Boston.

DR. PAUL A. TESCHNER:

Nov. 14—Longfellow School Parent Teacher Association, Oak Park, Ill.

Nov. 19—Roosevelt School Parent Teacher Association, Elmhurst, Ill.

Nov. 25—North Central College, Naperville, Ill.

Dec. 2—Woman's Club, Chilton, Wis.

Dec. 4, 5, 6—Fourth School Broadcast Conference, Chicago.

DR. NATHAN B. VAN ETEN:

Nov. 13—Southern Medical Association, Louisville, Ky.

Nov. 19—Westchester County Medical Society, White Plains, N. Y.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION AND PUBLIC HEALTH.)

ALABAMA

Examination for Director of Jefferson Hospital.—Applications are now being received to fill the position of director of Jefferson Hospital, Birmingham. An announcement appeared in *THE JOURNAL*, October 19, page 1385, outlining the qualifications, but a later notice states that the age limit has been eliminated from the requirements, although the applicant must be not less than 32 years of age. The stipulation that previous experience shall have been in a hospital of at least 150 beds has also been eliminated, but the applicant must have had not less than five years' experience as administrator of an approved general hospital caring for both private and charity patients. The closing date for applications has been extended from October 25 to November 10. Information may be secured from the Personnel Board of Jefferson County, Room 520, Courthouse, Birmingham, or from Dr. William H. Walsh, consultant to the board, 612 North Michigan Avenue, Chicago.

CALIFORNIA

Society News.—Dr. Dwight L. Wilbur, San Francisco, addressed the Los Angeles County Medical Association, October 17, on "Clinical Importance of the Vitamin B Complex."—The Los Angeles Society of Neurology and Psychiatry was addressed, October 16, by Drs. Norman Reider on "Influence of Early Training on Later Aphasic Manifestations" and Johannes M. Nielsen, "The Associative Function of the Minor Cerebral Hemisphere."—Among others, Dr. Victor Goodhill discussed "Fracture of the Larynx" before the Los Angeles Society of Ophthalmology and Otolaryngology, October 28.—A symposium on office gynecology was presented before the Alameda County Medical Association, Oakland, October 21, by Drs. Leonard Woods, John N. Ewer, John W. Sherrick and Thomas Floyd Bell, all of Oakland, and Woodburn K. Lamb, Berkeley.

COLORADO

The Friedman Lectures.—The William S. Friedman Lectures will be delivered, November 4-5, under the auspices of the National Jewish Hospital, Denver, in cooperation with the Medical Society of the City and County of Denver and the University of Colorado School of Medicine. The lecturers will be Drs. Edgar Mayer, assistant professor of clinical medicine, Cornell University Medical College, New York, and Oswald S. Lowsley, director, department of urology, James Buchanan Brady Foundation, New York. Dr. Mayer will speak on "Recent Advances in the Clinical Interpretation and Management of Pulmonary Tuberculosis" and "Pulmonary Tuberculosis in the Present Epidemiologic Phase" and Dr. Lowsley on "Surgical and Nonsurgical Treatment of Tuberculosis of the Genital and Urinary Tracts" and "Prostatic Surgery." Both physicians will conduct clinics. The lectures are financed by the Friedman Fund, which was established in 1938.

ILLINOIS

Southern Illinois Meeting.—The sixty-sixth annual meeting of the Southern Illinois Medical Association will be held in the high school gymnasium, Metropolis, November 14. Included among the out of town speakers will be:

Dr. Clyde E. Purcell, Paducah, Ky., Bronchoscopy.
Dr. Russell J. Blattner, St. Louis, Infant Feeding.
Dr. Gershon J. Thompson, Rochester, Minn., Prostatic Problems.
Dr. Adolph H. Conrad, St. Louis, Dermatology in General Practice.
Dr. William T. Pride, Memphis, Tenn., Anesthesia, Analgesia and Amnesia in Obstetrics.
Dr. Samuel B. Grant, St. Louis, Modern Care and Treatment of Pneumonia.
Dr. James S. Speed, Memphis, Tenn., Care of Commoner Fractures Encountered in General Practice.

Postgraduate Conference at Mattoon.—The Illinois State Medical Society is sponsoring a postgraduate course in Mattoon, November 7, with the Coles-Cumberland County Medical Society acting as host. The speakers will be:

Dr. Italo F. Volini, Chicago, Sulfanilamide and Allied Drugs; Indications, Contraindications, Dosage.

Dr. William C. Danforth, Evanston, Ill., Misguided Gynecologic Operations and the Consequences.
Dr. Willard O. Thompson, Chicago, Obesity, Types and Management.
Dr. Millard F. Arbuckle, St. Louis, Late Developments in Upper Respiratory Diseases.
Dr. Louis R. Limarzi, Chicago, Recent Advances and Treatment of Abnormal Blood Conditions.
Dr. Eugene F. Traut, Chicago, Chronic Arthritis, Medical Management.
Dr. John S. Coulter, Chicago, Chronic Arthritis, Management with Physical Therapy.

A symposium on diseases of the biliary tract will be presented in the evening by Drs. Manuel E. Lichtenstein and Karl A. Meyer, both of Chicago.

A conference was conducted in Bloomington, October 31, with the McLean County Medical Society acting as host and with the following speakers on the program:

Dr. James E. Graham, Springfield, Varicose Veins.
Dr. Wilber E. Post, Chicago, Arthritis.
Dr. Bert I. Beverly, Chicago, General Principles of Behavior in Children.
Dr. Henry Close Hesselstine, Chicago, Newer Endocrines in Gynecology.
Dr. Ralph A. Reis, Chicago, Spontaneous Abortions.

A symposium on the gallbladder and liver, with Drs. Andrew C. Ivy and Harry M. Richter, Chicago, as the speakers, concluded the session.

Chicago

Personal.—The Sisters of St. Anthony de Padua Hospital gave a dinner, October 9, in honor of four physicians who have given the hospital more than thirty-five years' continuous service. The physicians are Drs. Stephen E. Donlon and Max A. Weisskopf, who have been members of the staff since its foundation in 1896, and Drs. John D. McGregor and Fred J. E. Ehrmann.

Meeting on Chemotherapy.—Dr. John A. Kolmer, Philadelphia, will address the Chicago Medical Society, November 6, on "The Present Status of Chemotherapy." Discussions of "The Application of Chemotherapy in Medicine" will be presented by Drs. Robert W. Keeton, internal medicine; Warren H. Cole, surgery; Russell D. Herrold, urology; Ralph A. Reis, obstetrics, and Franklin J. Corper, pediatrics.

Society News.—The Chicago Orthopaedic Society was addressed, October 17, by Drs. Francis Walter Carruthers, Little Rock, Ark., on "Treatment of Fractures of Long Bones by a Removable Screw" and James S. Speed, Memphis, Tenn., "Treatment of Fractures Near Joints."—The Chicago Gynecological Society was addressed, October 18, by Drs. John H. Moore, Grand Forks, N. D., on "Late Effects of the Toxemias of Pregnancy" and Edwin C. Hamblen, Durham, N. C., "Observations on the Gynecic Employment of Equine Gonadotropins."—The Chicago Surgical Society was addressed, November 1, by Drs. Stephen A. Zieman on "Fibrosarcoma of the Soft Part of the Finger: Case Report"; Paul B. Magnuson, "Joint Débridement: Surgical Treatment of Certain Types of Arthritis," and Geza de Takats, "Surgical Approach to Hypertension."—Dr. John D. Ellis will discuss "Lesions of the Back Mistaken for Trauma" before the Chicago Society of Industrial Medicine and Surgery, November 4, and Dr. Frederick A. Jostes, St. Louis, "Evaluation of Manipulative Therapy for Back Conditions."—The Chicago Laryngological and Otolological Society will be addressed, November 4, by Drs. William E. Grove and Gerhard D. Straus, both of Milwaukee, on "Otitis Media—Meningitis—Labyrinthitis—Recovery with Retention of Function Through Chemotherapy Plus Radical Exposure Without Labyrinthectomy"; John R. Lindsay, "Chemotherapy in the Treatment of Otic Complications," and Paul A. Campbell, "A Few Medical Problems of Combat Aviation."—The Illinois Psychiatric Society will be addressed, November 7, by Drs. Abraham A. Low and Elizabeth P. MacDougall on "Combined Picrotoxin and Metrazol Treatment of Mental Patients"; Victor E. Gonda, "Treatment of Mental Disorders with Electrically Induced Convulsions," and Gerhart Pisk, Elgin, Ill., "Prognostic Observations in Insulin Treatment of Schizophrenia."

INDIANA

Graduate Course in Obstetrics.—The Tippecanoe County Medical Society, in cooperation with the state bureau of maternal and child health, will offer a postgraduate course in obstetrics at the Home Hospital, Lafayette, beginning November 7. The second meeting will be November 14, the third November 28 and the last December 5.

Dr. Ferree Named Director of Health.—Dr. John W. Ferree, since 1936 chief of the bureau of local health administration, state department of public health, has been appointed director of public health, succeeding Dr. Verne K. Harvey, resigned. Dr. Ferree graduated at Indiana University School

of Medicine, Indianapolis, in 1932. He also has a degree in public health from Johns Hopkins University School of Hygiene and Public Health.

Dr. Huber Wins Obstetricians' Prize.—Dr. Carl P. Huber, associate professor of obstetrics, Indiana University School of Medicine, Indianapolis, has received the 1940 award of the Central Association of Obstetricians and Gynecologists for the best clinical essay. The title of the paper, which was prepared with the assistance of Dr. Jack C. Shrader, 1940 graduate of the medical school and now an intern in the Indianapolis City Hospital, was "Blood Prothrombin Levels in the Newborn." Dr. Huber graduated at the University of Michigan Medical School, Ann Arbor, in 1928, where he served in the department of obstetrics and gynecology until 1936. He spent the following two years at the Chicago Lying-in Hospital and joined the faculty of Indiana University in 1938. Dr. Shrader received the Ravdin gold medal awarded to the student ranking highest scholastically in his class at the June commencement.

MAINE

Society News.—The Androscoggin County Medical Society was addressed, September 19, by Drs. Morris E. Goldman, Lewiston, on "Fractures of the Bones About the Hand" and Edwin Kay, Lewiston, "Placenta Praevia."—Among others, Dr. Duncan E. Reid, Boston, addressed the Kennebec County Medical Association, Gardiner, September 19, on "Use of X-Rays in Obstetrics."—Dr. Frederick T. Hill, Waterville, discussed "Chemotherapy in Relation to Otolaryngology" before the Piscataquis County Medical Association, September 19.

MINNESOTA

Mayo Memorial Proposed.—The Mayo Memorial Commission has been appointed by Gov. Harold E. Stassen to study a proposal for the establishment of a \$250,000 fund through public subscription throughout the world for a memorial to the late Drs. William J. and Charles H. Mayo. State Senator William B. Richardson, Rochester, is chairman of the commission, which is composed of seventeen representative citizens of Minnesota.

Society News.—The Minneapolis Clinical Club was addressed, October 10, by Drs. Carl W. Laymon on "Kodachrome Photography in Dermatology"; Harry W. Christian, "Factitious Proctitis Caused by Irradiation" and "Value of Macroscopic and Microscopic Examination of Excised Rectal and Anal Tissue," and James M. Hayes, "Gastro-Enterostomy" (a motion picture).—Dr. Wesley W. Spink addressed the Minnesota Pathological Society, October 15, in Minneapolis on "Pathogenesis and Treatment of Staphylococcal Infections."—The Wabasha County Medical Society was addressed in Plainview, October 10, by Drs. Earl W. Ellis, Elgin, on "Duties of Physicians in Relation to Medical Preparedness" and "Report of a Case of Ruptured Gastric Ulcer in a Diabetic Patient"; Floyd M. Feldman, Rochester, "Review of Knowledge Concerning Acute Poliomyelitis"; Clarence G. Ochsner, Wabasha, "Report on Appendectomies," and Miland E. Knapp, Minneapolis, "Physical Therapy in General Practice."

NEW JERSEY

New York University Sponsors Courses in Newark.—New York University College of Medicine is offering two postgraduate courses at the Newark City Hospital during 1940-1941. The first, which will begin November 6 and continue through December 4 on Wednesday and Friday afternoons, will be on peripheral vascular diseases. The work will be directed by Dr. Stuart Z. Hawkes, Newark. The second course will be on fractures, under the direction of Dr. Herbert A. Schulte, Newark, and will cover nine weeks, from February 5 to April 2, on Wednesday mornings. Applications should be sent to the Office of the Dean, New York University College of Medicine, 477 First Avenue, New York.

Society News.—Dr. John Carlisle Brown, Atlantic City, addressed the Medical Society of Cape May County at Cape May Court House, October 8, on "Toxemias of Pregnancy."—Dr. William E. Caldwell, New York, addressed the Essex County Medical Society, Newark, October 10, on "Prolonged First Stages of Labor."—Dr. Henry H. Ritter, New York, addressed the Atlantic County Medical Society, Atlantic City, October 18, on "What the General Practitioner Should Know About the Surgery of Trauma."—Dr. Jay Arthur Myers, Minneapolis, addressed the Bergen County Medical Society at

Bergen Pines, October 8, on "Follow-Up Work in Tuberculin Testing Surveys."—Dr. Chevalier L. Jackson, Philadelphia, addressed the Camden County Medical Society, Camden, October 1, on "Broncho-Esophagology in Relation to General Medicine."

NEW YORK

District Meetings.—The Fourth District Branch of the Medical Society of the State of New York held its annual meeting in Schenectady, October 1-2, with the following speakers, among others:

Dr. Abraham H. Aaron, Buffalo, Proprietary Medicines.
Dr. John E. Deitrick, New York, Acute Cardiovascular Emergencies.
Dr. Louis H. Bauer, Hempstead, Medical Care of the Indigent Sick.
Dr. Frederick F. McGauley, Schenectady, Treatment of Unusual Fractures.

The Eighth District Branch held its meeting at Niagara Falls, October 3, with the following speakers:

Dr. Noah Stanley Lincoln, Mount Morris, Diagnosis and Management of Early Pulmonary Tuberculosis.
Dr. Julius H. Hess, Chicago, Problems in the Care of the Premature Infant.
Dr. William P. Van Wagenen, Rochester, The Rationale of Common Procedures Used in the Care of Head Injuries.

Dr. Abraham H. Aaron, Buffalo, led a round table discussion on therapy, and there was also a program of motion pictures.

New York City

First Harvey Lecture.—Dr. Charles Armstrong, senior surgeon, U. S. Public Health Service, National Institute of Health, Washington, D. C., delivered the first Harvey Lecture of the season, October 31, at the New York Academy of Medicine. His subject was "Studies on Lymphocytic Choriomeningitis and Poliomyelitis."

Annual Hospital Fund Campaign.—The United Hospital Fund opened its sixty-second annual city-wide campaign, October 21, with a dinner at the Hotel Astor. Roy E. Larsen, president of Time Inc. and publisher of *Life*, is general chairman of the campaign, in which about 5,000 volunteer workers, representing eighty-nine voluntary hospitals, women's social service committees and auxiliaries and the Visiting Nurse Association of Brooklyn will participate.

The Salmon Lectures.—The eighth series of Thomas William Salmon Lectures will be delivered by Dr. Nolan D. C. Lewis, director of the New York State Psychiatric Institute and professor of psychiatry at Columbia University College of Physicians and Surgeons, on three successive Friday evenings at the New York Academy of Medicine. Dr. Lewis's general subject will be "The Pathway of Research in Psychiatry," and the individual lectures will be as follows:

November 8, Historical Perspectives of Psychiatric Thought.
November 15, Modern Ramifications in Psychiatric Thought.
November 22, Prospects for Future Achievement in Psychiatric Research.

Society News.—Drs. Edgar van Nuys Allen, Rochester, Minn., and Loyal Davis, Chicago, addressed a stated meeting of the New York Academy of Medicine, October 3, on medical and surgical aspects, respectively, of "Arterial Hypertension."—Dr. David I. Bassett addressed the Bronx Otolaryngological Society, September 24, on "Otitic Hydrocephalus."—Dr. Harvey B. Matthews, Brooklyn, discussed "Obstetric Shock" in a Friday afternoon lecture of the Medical Society of the County of Queens, October 4.—Dr. William Bierman, among others, addressed the New York Physical Therapy Society, October 9, on "Use of Physically Induced Pyrexia and Chemotherapy in Treatment of Subacute Bacterial Endocarditis."—Dr. Russel H. Patterson addressed the New York Surgical Society, October 9, on "Lymphogranuloma of the Rectum."—Drs. Louis E. Phaneuf, Boston, and Edward A. Schumann, Philadelphia, addressed the Medical Society of the County of Kings, Brooklyn, October 15, on "Cesarean Section" and "Certain Complications in Labor" respectively.

NORTH CAROLINA

Personal.—Dr. Allen J. Jervey Jr., Tryon, has been appointed district health officer for Rutherford and Polk counties to succeed Dr. Harold C. Whims, Rutherfordton, who was recently transferred to the Lincoln-Catawba district.

NORTH DAKOTA

Appointments to State Board.—Drs. Willard A. Wright, Williston, and Archibald D. McCannel, Minot, have been appointed to the state board of medical examiners to succeed Drs. William C. Fawcett, Starkweather, and Jesse W. Bowen, Dickinson. Dr. William A. Gerrish, Jamestown, was reappointed.

OHIO

Annual Institute on Cardiovascular Disease.—The Academy of Medicine of Cincinnati and the Heart Council of Cincinnati will present the seventh Cardiovascular Institute, November 12, on "Congestive Heart Failure." Clinical programs will be held at the Cincinnati General Hospital and the Children's Convalescent Home, the annual dinner of the Heart Council at the University Club and an evening meeting at the Academy of Medicine, with Dr. Tinsley R. Harrison, Nashville, Tenn., as the guest speaker.

Postgraduate Program.—The Summit County Medical Society presented its ninth annual Postgraduate Day, October 23, in Akron. The speakers, all of the faculty of the University of Michigan Medical School, Ann Arbor, were:

- Dr. Cyrus C. Sturgis, The Menace of Obesity, and The Diagnosis and Treatment of the So-Called Secondary Anemias.
Dr. John Alexander, Intrathoracic Tumors, and the Management of Bronchiectasis.
Dr. Walter G. Maddock, Problems in Severe Hyperthyroidism.
Dr. John M. Sheldon, Evaluation of Modern Drugs in Management of Allergic Patients, and the Diagnosis and Management of Eczema Patients.

PENNSYLVANIA

Warning of Impostor.—A man purporting to represent a firm called Hogan & Hogan at Germantown has been traveling through Pennsylvania taking orders for physicians' supplies, such as gauze, bandages and adhesive. Investigation by the Post Office at Germantown revealed that there is no such firm in the town, a Pennsylvania physician reports.

Memorial to Dr. Jesse Lazear.—Washington and Jefferson College, Washington, dedicated a new \$100,000 chemistry building, October 26, to the memory of Dr. Jesse W. Lazear, who died in Cuba in 1900 of yellow fever while serving as a member of the Yellow Fever Commission of the U. S. Army. Dr. Lazear was an alumnus of the college. John R. Kissinger, Huntington, Ind., and John J. Moran, Habana, Cuba, two of the group of soldiers who allowed themselves to be bitten by mosquitoes during the investigation, were guests at the dedication ceremonies. The college drama club presented Sidney Howard's play "Yellow Jack" as part of the ceremonies, which were held on the college's Founders' Day. At a banquet in the evening Dr. Philip S. Hench, Rochester, Minn., made an address on the work of the Yellow Fever Commission. The Jesse W. Lazear Chemistry Hall is one of three buildings dedicated, including one in honor of Edwin Linton, Ph.D., for many years professor of biology and geology at Washington and Jefferson and one of the founders of the Marine Biological Laboratory at Woods Hole, Mass.

Philadelphia

Annual Dinner of Ex-Residents.—The fifty-fourth annual dinner of the Association of Ex-Resident and Resident Physicians of the Philadelphia General Hospital will be held Tuesday, December 3, at the Midway Club, with Major Gen. Charles R. Reynolds, retired, director of the division of tuberculosis in the state department of health, as the guest of honor. Ex-residents who do not receive notices are requested to send their correct addresses to the secretary, Dr. George S. Wilson, 133 South Thirty-Sixth Street, Philadelphia.

Society News.—Dr. Joseph Stokes Jr. addressed the Philadelphia Pediatric Society, October 8, on "Clinical and Nutritional Problems Arising in Unoccupied France." Dr. Stokes recently spent several weeks in the area.—Drs. William T. Read Jr., Camden, N. J., and Leonard P. Lang, among others, addressed the Pathological Society of Philadelphia, October 10, on "Acutely Progressive Hodgkin's Disease" and "Tuberculosis of the Adrenal Simulating Thyroid Crisis" respectively.—Speakers before the Philadelphia Psychiatric Society, October 11, included Drs. Matthew T. Moore, Nathaniel W. Winkelman and Leon Solis-Cohen on "Asymptomatic Vertebral Fractures in Epilepsy."

RHODE ISLAND

Annual Clinic at Pawtucket.—The annual Intern Alumni Clinic Day will be held at Memorial Hospital, Pawtucket, November 6. Members of the staff will conduct clinics and the following members of the staff of Memorial Hospital for the Study of Cancer and Allied Diseases, New York, will give addresses: Drs. Hayes E. Martin on "Diagnosis and Treatment of Cancer of the Head and Neck"; Norman Treves, "Diagnosis and Treatment of Cancer of the Breast," and George T. Pack, "Diagnosis and Treatment of Cancer of the Gastrointestinal Tract."

WASHINGTON

State Obstetric Meeting.—Dr. Howard C. Stearns, Portland, Ore., was the guest speaker at the fall meeting of the Washington State Obstetrical Association at Spokane, October 5. At the morning session there were panel discussions of obstetric hemorrhage and in the afternoon reports of unusual cases were presented. Dr. Stearns conducted a round table discussion of antepartum care and presented two addresses on "Abruptio Placentae and Placenta Praevia" and "Prevention of Gynecologic Pathology."

Society News.—Drs. Kenneth K. Sherwood and Sylvester N. Berens, Seattle, addressed the Pierce County Medical Society, Tacoma, October 8, on "Arthritis and Focal Infection" and "The Intervertebral Disk" respectively.—Speakers before the King County Medical Society, Seattle, October 21, were Drs. Kenneth K. Sherwood, on "Medical Aspects of Postoperative Complications"; Joseph Gordon Spendlove, "Postoperative Complications of Anesthesia," and Edwin A. Nixon, "Postoperative Complications of Surgery."—Drs. Milburn H. Querna and Joseph W. Lynch addressed the Spokane County Medical Society, Spokane, October 10, on "Mechanics of Respiratory Function, Clinical Applications" and "Headache, Mechanism and Treatment" respectively.—Dr. Homer D. Dudley, Seattle, addressed the Walla Walla Valley Medical Society, Walla Walla, October 10, on "Acute Infections of the Hand."

GENERAL

"Nervous Insomnia" and Bad Checks.—A physician in Des Moines, Iowa, reports that a bad check swindler has again been imposing on the medical profession. A man in his early thirties, well groomed and intelligent, has been calling on physicians to get a prescription for "nervous insomnia." He claims to be a district sales manager for a large company just being transferred to the territory. The physician in his previous locality, he states, advised two prescriptions, one of phenobarbital for a daily sedative and one of seconal or nembutal if all else fails. He then asks where to take the prescription, cashing a small check at the drugstore on a local bank. The man is said to be a former student of osteopathy in Des Moines who was discharged for theft. In warning physicians, the Iowa physician calls attention to a peculiarity of rotation of the left eye.

American Society of Tropical Medicine.—The thirty-sixth annual meeting of the American Society of Tropical Medicine will be held in Louisville, Ky., November 12-15, in conjunction with the American Academy of Tropical Medicine and the National Malaria Committee during the annual session of the Southern Medical Association. The Walter Reed Medal will be awarded to Dr. Herbert C. Clark, Gorgas Memorial Institute of Tropical and Preventive Medicine, Inc., Panama, C. Z., and the fifth Charles Franklin Craig Lecture will be delivered by Dr. Rolla E. Dyer, U. S. Public Health Service, Washington, D. C., on "The Control of Typhus Fever." Among other speakers will be:

- Drs. Clarence A. Mills and Joseph W. Colvin, Cincinnati, Thiamine Protection Against the Depressive Effects of Tropical Heat.
John F. Kessel, Ph.D., Los Angeles, Recent Advances in the Study of Coccidioides in Infection.
Dr. Henry E. Meleney and Thomas L. Snyder, Ph.D., Nashville, Tenn., The Excystation of Endamoeba Histolytica in Bacteriologically Sterile Media.
Carl M. Johnson, Sc.D., Ancon, C. Z., Naturally Acquired Infections of Endamoeba Histolytica in Rhesus and Ateles Monkeys.
Ralph R. Parker, Ph.D., U. S. Public Health Service, Hamilton, Mont., Rocky Mountain Spotted Fever.
Drs. Harry Most and Milton Helpert, New York, Trichinosis in New York.

Dr. Louis L. Williams Jr., U. S. Public Health Service, will deliver his presidential address at the annual luncheon Wednesday on "Malaria Along the Burma Road." The Academy of Tropical Medicine will have its seventh annual dinner Thursday evening at the Hotel Seelbach, at which Dr. Charles S. Butler, U. S. Navy, retired, will give his presidential address on "Some Contributions of United States Naval Medical Officers to Science." The National Malaria Committee will hold its meeting Friday at the Seelbach under the chairmanship of W. G. Stromquist, health and safety department, Tennessee Valley Authority, Chattanooga, Tenn.

CORRECTION

Tattooing for Pruritus Ani.—In THE JOURNAL, October 12, page 1309, in the abstract of Turell's article the word "not" was omitted in the sentence beginning "Tattooing with mercuric sulfide is not done . . ."

LONDON

(From Our Regular Correspondent)

Sept. 14, 1940 (delayed).

The Treatment of Wound Shock

The Committee on Traumatic Shock and Blood Transfusion, appointed by the Medical Research Council, under the chairmanship of Prof. A. N. Drury, F.R.S., has presented a report on the treatment of wound shock. As the committee consists of the leading physiologists, biochemists, pathologists, physicians and surgeons of the day, the report is for the time the last word on the subject. Primary shock, which follows soon after injury and is not due to hemorrhage, resembles fainting. It responds to simple measures. The report deals at length only with secondary or wound shock, which develops insidiously some hours after injury. It is characterized by weakness, pallor and raised pulse rate and, in advanced cases, by lowered body temperature, sweating, low blood pressure, rapid thready pulse, vomiting and intense thirst. Medical officers should train themselves to recognize wound shock in its earliest stages, for it is then that treatment is likely to be effective. Wound shock closely resembles hemorrhage clinically and is likewise circulatory failure due to diminished blood volume, but loss of blood and plasma into the tissues produces the latter. Shock results from many factors besides loss of blood—fatigue, dehydration, pain and exposure to cold and wet—all of which demand attention in treatment. In some cases no more is necessary, but in the majority active steps to restore blood volume must be taken as early as possible. Reduction of blood volume is the constant and important feature and on its treatment success depends.

During military operations the most that can be done in advanced positions is to limit hemorrhage and loss of plasma by a firm bandage or tourniquet and by splinting to prevent pain and local loss of plasma due to movement of a fractured limb during transportation. The wounded must be protected from cold, and it is of great importance to give water freely and repeatedly except to those who are unconscious or have abdominal wounds. It should preferably contain 1 teaspoon of salt to the pint. The army transfusion apparatus allows blood or plasma to be administered at least as far forward as main dressing stations. Open wounds of the chest should be closed immediately, as otherwise they have a high mortality.

A patient unfit by reason of shock for immediate operation should be put in a resuscitation ward, where greater rest and quiet can be ensured than in a busy general ward. Wet and dirty clothes must be cut off with as little disturbance as possible and the patient should be clothed in warm pajamas and the bed warmed. For the relief of pain morphine from one-fourth to one-half grain (0.016 to 0.032 Gm.) subcutaneously is of exceptional value. When the circulation is too slow for quick absorption an almost immediate effect can be obtained by intravenous injection of up to one-fourth grain. The most valuable single method for combating shock is blood transfusion. Whole blood is of proved value, but human plasma or serum, because of their superior keeping qualities, are more convenient under field conditions. In extensive burns, in which reduction of blood volume is due entirely to loss of plasma, replacement by plasma or serum is theoretically correct. Even in hemorrhage, serum proteins and an adequate blood pressure may be of greater value than an increase of oxygen-carrying power. When blood, plasma or serum is not available, isotonic saline or dextrose solution may be used, but the restoration of blood volume is only transient by intravenous infusion of these solutions and is not devoid of risk. Because of the dehydration, repeated and copious drinking of fluids should be encouraged, with the exceptions mentioned. If necessary, the rectal route

may be used. Oxygen should be given to all who manifest cyanosis of the lips, ears or nails. It is especially necessary in any interference with respiration, as in chest wounds. In cases of infected wounds, absorption of toxins aggravates shock. Infected tissue must therefore be promptly removed and chemotherapy and other forms of treatment given. For cases requiring anesthesia, gas and oxygen, combined with ether, if necessary, is the mixture of choice, provided a skilled anesthetist and apparatus are available; otherwise ether alone should be used. Chloroform or spinal anesthesia should not be employed. The administration of an anesthetic to a shocked patient requires special care.

The Protection of Glass in Hospitals

Air raids have given rise to many problems in connection with the security of hospitals. The Research and Experiments Branch of the Ministry of Home Security has issued a memorandum on the protection of glass in hospitals. Three ways are suggested to minimize the scattering of glass from windows: (1) by covering the windows with wire netting of half inch or smaller mesh fixed to detachable frames, (2) by covering them inside with light weight screens which will cause the broken glass to fall close to the window and (3) by covering the glass with "anti-scatter material." The last can be done in four ways, which, in the order of effectiveness, are as follows: (a) Strong textile netting or some other fabric is stuck firmly to the glass. This is best applied with a preparation insoluble in water as varnish or lacquer. Thick and tough paper may be applied; crisscross strips are not recommended. (b) Cellulose film with varnish or lacquer as a waterproof coat is used. (c) Strips of material not less than 1½ inches wide and spaced to give not more than 6 inches of clear glass between the strips are used. (d) Liquid coatings, such as rubber latex, are applied but are not effective for panes more than 4 square feet.

It is recommended that all glass in operating rooms, except that in utensils and suspended light fittings, be removed. Window openings should be completely bricked up or barricaded and any roof-light opening would be covered by concrete slabs, sandbags or timber. If this is done and the operation light is a single freely suspended unit, fracture of the glass is not likely.

Medical War Relief Fund

As the benevolent funds of the medical profession are hard put to provide for ordinary cases of hardship, a special fund has been established for the temporary assistance of physicians and their dependents who are in financial straits from war conditions. For the organization of this fund a committee has been formed consisting of officers of the British Medical Association, the presidents of the Royal Colleges of Physicians, Surgeons and Obstetricians and Gynecologists, the chairman of the Charities Committee of the British Medical Association and the president of the Royal Medical Benevolent Fund. The sum of \$13,500 has been collected in a short time. As the medical profession has suffered less than other professions from the disturbances of the war, it is thought that it should itself come to the assistance of its own members.

Marriages

HARRY D. FEINBERG, Long Branch, N. J., to Miss Minna Liebesman of Asbury Park, June 28.

BLANCHARD FRED FORD JR., Clover, S. C., to Miss Marjorie Nelle Wells at Bennettsville, July 6.

WILLIAM J. EGAN, Boston, to Miss Mary J. Sullivan of Newton Highlands, Mass., July 10.

SAMUEL ARTHUR PURVES, Des Plaines, Ill., to Miss Rae McKnight of Boston, July 13.

WILLIAM COHEN, Portland, Ore., to Dr. STELLA FISHER of New York, June 30.

Deaths

Charles Nicoll Bancker Camac, Altadena, Calif.; University of Pennsylvania Department of Medicine, Philadelphia, 1895; instructor of physiology at his alma mater in 1895; instructor of physical diagnosis, chief of medical clinic, lecturer in medicine from 1905 to 1909 and professor of clinical medicine, 1909-1910, at the Cornell University Medical College, New York; assistant professor of clinical medicine at Columbia University College of Physicians and Surgeons, New York, from 1910 to 1938; emeritus professor of internal medicine at the New York Polyclinic Medical School and Hospital; visiting physician from 1899 to 1916 and consulting physician from 1916 to 1935 at the New York City Hospital; served during the World War; member of the Association of American Physicians; director of medicine, Gouverneur Hospital of Bellevue and Allied Hospitals, New York, from 1916 to 1923; author of "Imhotep to Harvey: Backgrounds of Medical History"; aged 72; died, September 27.

Joseph Patrick Brennan, Buffalo; University of Buffalo School of Medicine, 1908; member of the Medical Society of the State of New York; served during the World War; past president of the Buffalo Academy of Medicine; on the staffs of the Emergency Hospital of the Sisters of Charity, St. Mary's Infant Asylum and Maternity Hospital and the Millard Fillmore Hospital; aged 56; died, September 28, of coronary thrombosis.

Philip Eugene Garrison ♂ Surgeon Lieutenant Commander, U. S. Navy, retired, Ridgewood, N. J.; George Washington University School of Medicine, Washington, D. C., 1906; entered the navy in 1906 and retired in 1933 for incapacity resulting from an incident of service; aged 62; died, September 22, in the United States Naval Hospital, Brooklyn, of carcinoma of the liver and acute nephritis.

Thomas Lafayette Walker Bailey, Clinton, S. C.; Medical Department of Grant University, Chattanooga, Tenn., 1893; member of the South Carolina Medical Association; for many years trustee of the local schools; past president of the Laurens County Medical Society; aged 70; died, September 29, in the South Carolina Sanatorium, State Park, of pulmonary tuberculosis and cerebral hemorrhage.

John Clarence Smith, Jackson, Mich.; University of Michigan Homeopathic Medical School, Ann Arbor, 1907; member of the Michigan State Medical Society; past president of the Jackson County Medical Society; member of the board of managers and on the staff of the W. A. Foote Memorial Hospital; on the staff of the Mercy Hospital; aged 58; died, September 3, of coronary disease.

Wilson Kirt Dyer ♂ El Reno, Okla.; Eclectic Medical Institute, Cincinnati, 1908; member of the Illinois State Medical Society and the American Psychiatric Association; chief medical officer of the Federal Reformatory; formerly on the staffs of the East Moline (Ill.) State Hospital and the Peoria (Ill.) State Hospital; aged 55; died, September 20, of coronary thrombosis.

Joseph Lawrence Adams, Asheville, N. C.; Jefferson Medical College of Philadelphia, 1910; member of the Medical Society of the State of North Carolina; served during the World War; on the staff of the Asheville Mission Hospital and the Aston Park Hospital; aged 55; died, September 27, of intestinal hemorrhage and hypertensive heart disease.

Frederic Almon Thayer ♂ Beloit, Wis.; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1903; past president of the Rock County Medical Society; on the staff of the Beloit Municipal Hospital; aged 68; died, September 5, of coronary embolism.

Clement Dunham Smith ♂ Dayton, Ohio; Medical College of Ohio, Cincinnati, 1901; past president of the Montgomery County Medical Society; for many years on the staff of St. Elizabeth's Hospital; aged 62; died, September 4, in the Miami Valley Hospital of cerebral hemorrhage.

Louis Austin Bolling, Otterbein, Ind.; St. Louis College of Physicians and Surgeons, 1897; member of the Indiana State Medical Association; served during the World War; formerly on the staff of the Epworth Hospital, South Bend; aged 73; died, September 10, of heart disease.

Vern Leonard Hamilton, Pendleton, Ore.; Willamette University Medical Department, Salem, 1913; member of the Oregon State Medical Society; aged 57; died, September 13, of injuries received when he was struck by an automobile.

Harold Rowland Whiteside, Redding, Calif.; University of Oregon Medical School, Portland, 1933; member of the California Medical Association; aged 36; died in September at Sacramento of anterior poliomyelitis, bulbar type.

Charles Wallington Alden, Saginaw, Mich.; Bellevue Hospital Medical College, New York, 1877; formerly president of the city board of health, health officer and county coroner; aged 82; died, September 12, of a fractured hip.

Phillip Francis Hickey ♂ Smethport, Pa.; St. Louis University School of Medicine, 1933; aged 31; on the staff of the Kane (Pa.) Community Hospital, where he died, September 19, of injuries received in an automobile accident.

Wallace Ray Swartzwelder, York, Pa.; University of Maryland School of Medicine, Baltimore, 1927; member of the Medical Society of the State of Pennsylvania; aged 40; died in September of a self-inflicted bullet wound.

John O. Handley, Sycamore, Ala.; Memphis (Tenn.) Hospital Medical College, 1904; member of the Medical Association of the State of Alabama; died in September at the Citizens' Hospital, Talladega, of a gunshot wound.

Francis Johnston Sloane, Princeton, N. J.; Columbia University College of Physicians and Surgeons, New York, 1908; aged 56; was killed, September 5, near Mexico City, Mexico, in an automobile accident.

Perkins Glover, Arvon, Va.; Medical College of Virginia, Richmond, 1901; member of the Medical Society of Virginia; member of the county board of health; aged 66; died, September 5, of coronary thrombosis.

Homer H. Gates, Franklin, La.; Medical Department of Tulane University of Louisiana, New Orleans, 1899; member of the Louisiana State Medical Society; aged 64; died, September 27, of angina pectoris.

Albert Sidney Jarvis, Troup, Texas; University of Louisville (Ky.) Medical Department, 1894; at one time postmaster; formerly bank president; aged 72; died, September 7, of coronary occlusion.

Hiram D. Vaughtner, Byers, Texas; Memphis (Tenn.) Hospital Medical College, 1903; member of the State Medical Association of Texas; aged 73; died, September 10, of cerebral hemorrhage.

Lawson Silas Henley, Huntington, W. Va.; University of Louisville (Ky.) Medical Department, 1905; member of the West Virginia State Medical Association; aged 67; died, September 16.

Max Dobrow, Chicago Heights, Ill.; Jenner Medical College, Chicago, 1917; for many years city police physician; aged 56; died, September 20, in St. James Hospital of appendicitis.

Nicholas Matthew Crofts ♂ North Adams, Mass.; Baltimore Medical College, 1898; served during the World War; aged 74; died, September 17, of coronary thrombosis.

George Frederic Cullens, New Albany, Miss.; Memphis (Tenn.) Hospital Medical College, 1892; aged 69; died, September 15, of aortic regurgitation and myocarditis.

Harvey T. Wickert, Emmaus, Pa.; University of Pennsylvania Department of Medicine, Philadelphia, 1876; aged 85; died, September 11, of cerebral hemorrhage.

Jeremiah W. Trueblood, Monroe City, Ind.; Hospital College of Medicine, Louisville, Ky., 1891; aged 88; died, September 6, of uremia and chronic nephritis.

Melissa Evelyn Thompson Coppin, Philadelphia; Woman's Medical College of Pennsylvania, Philadelphia, 1910; aged 62; died, September 27, of acute endocarditis.

Julia Helen Bass, San Antonio, Texas (licensed in Texas by years of practice); aged 82; died, September 25, of acute pyelocystitis, uremia and arteriosclerosis.

Henry G. Brueckbauer, Sheboygan, Wis.; Homeopathic Medical College of Missouri, St. Louis, 1904; aged 62; died, September 16, of coronary thrombosis.

Louis Woodruff Armstrong ♂ Danville, Ind.; University of Maryland School of Medicine, Baltimore, 1900; aged 64; died, September 19, of angina pectoris.

Thomas Clifford Burnes, Randolph, Vt.; University of Vermont College of Medicine, Burlington, 1937; aged 27; died, September 9, of cerebral hemorrhage.

George Temple Beckett, Arlington, Ind.; University of Indianapolis Medical Department, 1899; aged 68; died, September 28, of coronary thrombosis.

David Marion Higgins ♂ Gainesville, Texas; Hospital College of Medicine, Louisville, Ky., 1893; aged 72; died, September 16, of coronary thrombosis.

Bureau of Investigation

FONG WAN, THE CHINESE HERBALIST

Herbert Corey, in *Nation's Business* for September 1940, under the heading "Washington and Your Business," submits the following item:

"Ever since the introduction of the Logan-Walter bill for the bridling and saddling of the government bureaus interest in their oddities has been growing. Here's a sample:

"The Post Office Department barred a Chinese doctor from the mails. He went to court, alleging that the drugs he used had been in the Chinese materia medica for 2,000 years, and produced many witnesses who testified that the Chinese drugs had cured them. The verdict of the court was in his favor.

"The Post Office still bars him from the mails."

Obviously Corey means to imply by this that since the Chinese "doctor" was found not guilty in court, the order barring him from the mails should no longer be in force and that in some unspecified way the Post Office Department is acting in disregard to the considered judgment of a court of record. While THE JOURNAL holds no brief for the pronounced extension of administrative agencies and their powers, the item quoted above seems to be unjust to the Post Office Department.

This Bureau cannot be positive as to which case Corey is referring to, but the case of one Fong Wan does meet the facts referred to by Corey. This is not the first time that Fong Wan has had the attention of this Bureau. As a matter of fact, THE JOURNAL for June 6, 1931, contained an article concerning him and a fraud order which was issued the previous year and which is still in effect.

This fraud order was issued in accordance with what has often been referred to as the Fraud Order Law (U. S. Code, Title 39, Sec. 259), which reads in part as follows:

"The Postmaster General may, upon evidence satisfactory to him that . . . any person or company is conducting any scheme or device for obtaining money or property of any kind through the mails by means of false and fraudulent pretenses, representations, or promises, instruct postmasters at any post office at which registered letters or any other letters or mail matter arrive directed to any such person or company . . . to return all such mail matter to the postmaster at the office at which it was originally mailed, with the word 'Fraudulent' plainly written or stamped upon the outside thereof; and all such mail matter so returned to such postmasters shall be by them returned to the writers thereof, under such regulations as the Postmaster General may prescribe.

The statute is not *penal*, it is not a *criminal* statute. It simply authorizes the Postmaster General to protect the public from palpable frauds coming to his attention. Any person to whom the mails have been so closed presumably has adequate *civil* remedies, if he considers himself aggrieved, to compel the use of the mails.

Some time later Fong Wan was indicted under the Federal Criminal Laws for using the mails to defraud. He did not go to court as might be inferred from Corey's item to question the fraud order and to ask the courts to require the Post Office to let him use the mails, but because he was accused of violating U. S. Code, Title 18, Sec. 338, the material part of which reads:

"Whoever, having devised or intending to devise any scheme or artifice to defraud, or for obtaining money or property by means of false or fraudulent pretenses, representations or promises . . . shall, for the purpose of executing such scheme or artifice or attempting so to do, place, or cause to be placed, any letter, postal card, package, writing, circular, pamphlet, or advertisement, in any post office, or station thereof, or street or other letter box of the United States, or authorized depository for mail matter, to be sent or delivered by the Post Office Establishment of the United States, shall be fined not more than \$1,000, or imprisoned not more than 5 years, or both."

The intent of the authorities was to see that he was punished criminally for his acts. *He was not convicted.* But this has absolutely no relation to the fraud order. This may be illustrated by noting that the acquittal of a physician on a *criminal* charge of abortion will not prevent the appropriate licensing agency from revoking his license to practice for performing an *illegal* abortion.

Now let us see just what Fong Wan has done to warrant the issuance and continuance of the fraud order.

The evidence indicates that Fong Wan, who, so far as THE JOURNAL knows, has never been licensed to practice any form of the healing art in any state in the Union, has offered treat-

ments for practically every disease under the sun. For example, one of his remedies is offered for diabetes and he was promoting it as a cure in 1930. If it really did cure, every diabetic person in California would be availing himself of the opportunity of taking it by this time. Thus there should be no more deaths from diabetes in California.

Wan has promoted his products on the basis of the teachings of a former Chinese emperor known as Shin Nong, which, he says, means "Divine Farmer." According to some of the publicity of the Fong Wan Herb Company of Oakland:

"He [Shin Nong] believed that all things on earth were included in five natural elements: water, fire, vegetation, mineral and earth. The color predominating in the vegetation element is green. Because the liquid contained in the gall bladder and the juices secreted by the liver are greenish, he concluded that the gall bladder and liver belonged to the vegetation element. The natural color of the fire element is red. As the heart controls the circulation of the blood of the body, and as the blood is red, he said that the heart belonged to the fire element. The natural taste of the water element is salty. As the urine, which passes through the kidneys into the bladder, is salty, these two organs were classified under the water element. The natural color of the earth element is yellow. As Shin Nong believed that the stomach gets its power from the spleen, and as the gastric juice of the stomach is yellow, he classified the spleen and the stomach as belonging to the earth element. As the color of the natural element in mineral is white, and as the lungs are white, he concluded that they belonged to the mineral element."

On Dec. 14, 1939, the Federal Trade Commission at Washington issued a complaint against Fong Wan, charging him with misrepresentation in advertising matter, in newspapers and periodicals and in a booklet designated "Herb Lore" (from which the foregoing quotation concerning Shin Nong was taken) concerning the remedial benefits of Chinese herbs sold and distributed by Fong Wan and his co-partners. The complaint charged that in advertising matter the respondents represented that the herbs sold by them "are a remedy, cure and effective treatment for heart trouble, high blood pressure, colds, influenza, asthma, pyorrhea, blood disorders, cross eyes and other eye troubles, cancer, stomach troubles, dysentery, pains, dizziness, hardening of the arteries, gout, bronchial trouble, coughs, sinus trouble, liver and gallbladder troubles, diabetes and other disorders of the kidneys and bladder, nervous attacks and disorders, arthritis, obesity, headaches, neuritis and piles, and that they stop pain and give permanent relief from asthma and other disorders."

The complaint alleged that "in truth and in fact the respondents' Chinese herbs are not a remedy or cure for any of the ailments or diseases named; that they do not and cannot wash away any diseases from the human body; that Fong Poy or Fong Wan is not able to diagnose or heal diseases or ailments, nor has he restored the health of any persons by the use of Chinese herbs."

The outcome of this case is, of course, not known at the present time. It is interesting to note, however, that on February 26 of this year Fong Wan issued a fourteen page advertisement in the *Oakland Tribune*, reproducing some of the testimony that had been transcribed at the Federal Trade Commission hearing in connection with the complaint noted. It has been reported to us that Fong Wan paid \$4,850 for the printing of this advertisement, which comprised a section of the *Oakland Tribune*. The heading of this advertisement was "Marvelous Results Derived From Fong Wan Chinese Herbs Have Been Testified Before the Federal Trade Commission at San Francisco, California," and the subheading read "Numerous Witnesses at Commission Hearing Tell of Instances Where They Were Relieved by Use of Chinese Herbs. Following is Copy of Official Transcript of Testimony in Fong Wan Hearing." On the final page of this section of the *Oakland Tribune* there appeared some excerpts from the booklet "Herb Lore," and under the heading "Unparalleled Success of Fong Wan, Herbalist" it is stated that since the establishment of his herb business in Oakland in 1915 he has won more than twenty cases in the police court. Again quoting from the advertisement:

"In 1924-1925, some lawyers and Chinese women combined to sue him for \$25,000 in a slander suit (that had been predicted in his horoscope at the time of his birth). He won this case in both the Appellate and the State Supreme Courts. This suit cost the plaintiffs at least \$3,000."

He claimed further that "In 1925 the Anti-Herb Bill was introduced. An investigation by the State Assembly at Sacra-

mento was started. It cost the State of California no less than \$6,000 (and showed many indications that it was a bill of graft)."

Finally, it is claimed that "For more than 20 years Fong Wan has realized that the medicos, after having failed in their attempts to put the chiropractors and healers of other schools out of business, would center their attention on the Chinese herbalists. Being the most renowned herbalist in America, Fong Wan also suspected that he would be the target."

If one may judge by the transcript of the Federal Trade Commission hearing which is detailed in his advertisement, the principal defense of this herbalist is the testimony of individuals who claim to have been cured, and, incidentally, individuals who have submitted testimonials which are used in advertising the products. The fact that these individuals are not qualified either to diagnose their own condition or to determine whether or not they have been cured of that condition indicates that the evidence for the usefulness of his preparations is far from scientific.

A few excerpts from the booklet "Herb Lore" will serve to illustrate the type of hokum which it contains:

"It is customary in America for people to have electric toasters on their table and to make lots of toast. Even sick persons in the hospitals are frequently served hot toast without regard to their ailments. Most people never stop to think that toast takes in the direct fire heat, and that the butter, which is fat-giving, adds more heat to the body. A little toast occasionally does no harm, but if a person eats hot buttered toast every day, some of the following ailments will appear sooner or later: headache, tiredness of the eyes, sinus inflammation, stomach ulcers, cold sores, canker sores, etc. If one wishes to avoid overheating the system, it is best to eat steamed or boiled food."

We also find:

"In the United States of America, due mainly to the persistency of the Chinese herbalists themselves and their willingness to endure persecution for the sake of their profession, the use of Chinese Herbal Remedies has been gradually introduced. At the present time, scientists are keenly interested in Chinese Herbs. The chemists of the University of California and of other universities in the United States are making intensive studies and carrying on numerous experiments in order to determine scientifically the exact effects of certain Chinese Herbs upon the human system."

Such a statement as the final one in the preceding paragraph would indicate that the promoter has little concern as to whether or not scientific experimentation will demonstrate just how ineffective these remedies will be found to be. Elsewhere in the booklet Fong Wan expresses the belief that the scientists will have trouble determining the efficacy of the remedies:

"Extracts of various Chinese herbal remedies have been subjected to chemical processes in order to precipitate their elements. However, many kinds of herbs and roots show nothing in the test tube; consequently, the chemists cannot determine their uses. For example, a chemist is never able to discover the elements of the Ginseng Root which is a wonderful remedy in building up the air circulation in the body. For the past fifty centuries, the Chinese have used Ginseng Root to strengthen the air circulation and have combined it with other herbal remedies to improve the blood circulation."

"Articles written by chemists or pharmacists frequently appear in the newspapers ridiculing the Chinese as being superstitious in believing that Ginseng has great medicinal value. Because these writers cannot see the curling of the smoke, they say there is no fire."

In case the reader might think that some herbs were drugs or vice versa, the following statement is made:

"Naturally, when we look at the words 'drug' and 'herb,' we think of them as being related. Each consists of four letters. There, however, the resemblance ends."

On the basis of such statements, the reader is introduced to herb lore. The remainder of the booklet is made up of chapters concerning the various organs of the human body, for example the stomach, the spleen, the heart, the lungs and the throat. Each chapter opens with the Chinese theory regarding the subject and closes with testimonials of those who claim to have suffered from diseases affecting those organs and to have obtained relief from the use of Fong Wan's remedies. His testimonial writers claim cures for everything under the sun. One individual, Gregory G. Souza of Oakland, Calif., stated that he had a very sore throat which the doctor pronounced a case of diphtheria. But, remembering that Fong Wan had rid his sister of a long-standing cough which the doctors had called consumption, and restored his cousin, who suffered from dropsy, to perfect health, he decided to try him. Within two hours after taking Fong Wan's remedy, all the pain in his throat was gone and the swelling had subsided.

As an afterthought, Souza added: "Recently I suffered from Cancer of the Navel and the pain became so severe that I was confined to my bed for three weeks. Again I had recourse to Fong Wan, and I am happy to say that the cancer has now entirely disappeared and I am well and strong."

Mrs. Emma Kennedy of Vallejo, Calif., wrote as follows:

"To Whom It May Concern:

I suffered from Diabetes, Heart Trouble and Nerves for some time. It seemed as though no relief could be had anywhere. Two months ago, however, I began to drink Fong Wan Herbs and I soon realized their healing power. I am happy to testify that my troubles have been entirely overcome and that I now feel like a new woman. I am writing these few lines in order that others so afflicted may know where to find relief."

Citizens of the United States should be exceedingly proud that federal laws permit a fraud order to remain in force against an individual who is obviously engaged in fraudulent practices, even though he has been able to obtain a verdict of not guilty in a case in the courts under what is referred to as the Fraud Law. The postal authorities are to be commended for continuing the fraud order and thus interfering to some extent with the activities of this individual. Sooner or later the state authorities of California may enter the picture. In the meantime, it will be interesting to note the outcome of the Federal Trade Commission case.

MISBRANDED PRODUCTS

Abstracts of Notices of Judgment Issued by the Food and Drug Administration of the United States Department of Agriculture

[EDITORIAL NOTE.—These Notices of Judgment are issued under the Food, Drug and Cosmetic Act and in cases in which they refer to drugs and devices they are designated D. D. N. J., cosmetics C. N. J., and foods F. N. J. The abstracts that follow are given in the briefest possible form: (1) the name of the product; (2) the name of the manufacturer, shipper or consigner; (3) the composition; (4) the type of nostrum; (5) the reason for the charge of misbranding, and (6) the date of issuance of the Notice of Judgment—which is considerably later than the date of the seizure of the product and somewhat later than the conclusion of the case by the Food and Drug Administration.]

Bad-Ex-Salts.—American Laboratories, Carlisle, Pa., and E. J. Barry, Inc., New York. Composition included tartar emetic. Laxative and tonic. Dangerous to health when used as directed.—[D. D. N. J., F. D. C. 44; May 1940.]

Bromo-Seltzer.—Emerson Drug Co., Baltimore. Composition: an effervescent mixture of acetanilid, sodium bromide and caffeine. For headache, neuralgia and disordered stomach and nerves. Dangerous to health when used as directed.—[D. D. N. J., F. D. C. 81; May 1940.]

Cal-co-ein.—Crescent-Kelvan Co., Philadelphia. Composition: calcium salts of benzoic acid and cinchophen. For arthritis. Declared potentially injurious if used as directed.—[D. D. N. J., F. D. C. 10 and 77; May 1940.]

Cephalgine Tablets.—Cephalgine Co., Spencer, Mass. Composition: acetanilid, caffeine and camphor. For simple headaches, neuralgia and muscular pains. Dangerous to health when used as recommended.—[D. D. N. J., F. D. C. 80; May 1940.]

Guerlain Lipsticks (Nos. 144, 145 and 160).—Guerlain, Inc., New York. Composition included cadmium and selenium. Declared potentially injurious if used as directed.—[C. N. J., F. D. C. 16; May 1940.]

Hydecocyl.—Murray Oil Products Company and Industrial Oil Products Corporation, Los Angeles. Composition: not more than 50 U. S. P. units of vitamin D per gram, whereas represented to contain 85 such units.—[D. D. N. J., F. D. C. 84; May 1940.]

Magic-Di-Stik Lash and Brow Dye.—Magic-Di-Stik Co., Los Angeles. Composition included paraphenylenediamine. Declared potentially injurious if used as directed.—[C. N. J., F. D. C. 3 and 4; May 1940.]

Madam Marva Hair Coloring.—Madam Marva Products Co., St. Louis. Composition included paraphenylenediamine. Declared potentially injurious if used as directed.—[C. N. J., F. D. C. 14; May 1940.]

Tru-Lax Mint Flavored Chewing Laxative.—Peltz-Kauffer Co., Inc., South Bend, Ind. Composition included 1 grain of phenolphthalein. Dangerous to health if used as directed.—[D. D. N. J., F. D. C. 43; May 1940.]

Universal Formula.—Universal Antiseptic & Research Laboratories, Inc., Bristol, Tenn. Composition: essentially alum, borax, sugar, water, carboic acid (1.84 per cent) and small proportions of aromatic substances, including thymol and sage. Not antiseptic when diluted as directed on label. Falsely represented as efficacious for sinus trouble, quinsy, asthma, catarrh, tonsillitis, croup and a great many other disorders.—[D. D. N. J., F. D. C. 46; May 1940.]

Queries and Minor Notes

THE ANSWERS HERE PUBLISHED HAVE BEEN PREPARED BY COMPETENT AUTHORITIES. THEY DO NOT, HOWEVER, REPRESENT THE OPINIONS OF ANY OFFICIAL BODIES UNLESS SPECIFICALLY STATED IN THE REPLY. ANONYMOUS COMMUNICATIONS AND QUERIES ON POSTAL CARDS WILL NOT BE NOTICED. EVERY LETTER MUST CONTAIN THE WRITER'S NAME AND ADDRESS, BUT THESE WILL BE OMITTED ON REQUEST.

ADDICTION TO AMPHETAMINE (BENZEDRINE) SULFATE

To the Editor:—A man who has become addicted to the use of benzedrine sulfate has been taking the drug now for nearly two and one-half years on an average of a dozen 10 mg. tablets daily and has taken as many as twenty-four a day. Briefly, he was a confirmed alcoholic addict and after a terrific debauch in February 1938 he wanted something to pep him up and also something to take when he felt the craving for alcohol. More in the spirit of experimentation than anything else I prescribed benzedrine sulfate tablets, two daily. I didn't see him for several months; then he came looking fine; he had gained weight and claimed that the taking of the drug had completely banished his desire for alcohol. He said, however, that if he missed taking the benzedrine he would get a terrific craving. I warned him at that time about the possible danger of the drug but decided it was the lesser of two evils. I lost track of him for some time. A few weeks ago he turned up for a prescription, since a new state law recently passed requires one for all such drugs. He then told me he had been taking them continuously and at the rate of ten or twelve daily. He is an automobile salesman and claims that he can't carry on his daily routine without them. Withdrawal causes nervousness, exhaustive fatigue and inability to think straight and, believe it or not, sleeplessness. He has not lost any weight since I first saw him and appears to be in fairly good health. In spite of the fact that he has been a lifetime drunkard he has not touched a drop since he began taking the tablets. He is a white man aged 49, he weighs 123 pounds (56 Kg.) and his blood pressure is 115 systolic, 90 diastolic. He is in good health otherwise except for a hernia he has had for twenty years and a recently developed fistula in ano. Please advise me how I can get him off the drug, also what organic effects it will cause if he continues its use. Please bear in mind the danger of his resuming his alcoholic course if I suddenly withdraw the drug.

L. J. Hahne, M.D., Savannah, Ga.

ANSWER:—Until recently there have been no specific reports of cases of addiction to amphetamine (benzedrine) sulfate, although the Council on Pharmacy and Chemistry has repeatedly warned physicians against such a possibility ever since this was first pointed out in its report on the drug (Report of the Council on Pharmacy and Chemistry, Present Status of Benzedrine Sulfate, *THE JOURNAL*, Dec. 18, 1937, p. 2064). At that time the question of tolerance to the drug and the possibility of cumulative effects were not definitely settled. S. P. Waud has since reported (The Effects of Toxic Doses of Benzyl Methyl Carbinamine (Benzedrine) in Man, *THE JOURNAL*, Jan. 15, 1938, p. 206) that a definite tolerance for amphetamine is slowly built up and that increasing doses are necessary to produce the original effects. While indicating that the question of addiction was not settled at that time, he pointed to its likelihood as a possibility because "most drugs that produce a pleasant effect on the brain (either stimulating or quieting in nature) have their addicts." He also indicated that the stimulation of the central nervous system is definite but relatively temporary and is always followed by fatigue and mental depression when toxic doses of amphetamine are absorbed. *THE JOURNAL* later published an editorial (Benzedrine Sulfate—A Warning, March 19, 1938, p. 901) warning against the use of the drug for the treatment of obesity in otherwise normal individuals by reducing the appetite, because of the danger that such use may produce craving and even addiction in some instances. Furthermore, severe reaction and even death have been reported following the indiscriminate use of amphetamine sulfate (Apfelberg, Benjamin: A Case of Benzedrine Sulfate Poisoning, *THE JOURNAL*, Feb. 19, 1938, p. 575. Smith, L. C.: Collapse with Death Following the Use of Amphetamine Sulfate, *ibid.*, Sept. 9, 1939, p. 1022).

A case of addiction resulting from the continued use of amphetamine sulfate has recently been reported (Friedenberg, Sidney: Addiction to Amphetamine Sulfate, *ibid.*, March 16, 1940, p. 956). The drug was administered over a period of six months in doses of from 5 to 10 mg. twice a day for the treatment of obesity. Reduction of the dosage after this time was followed by fatigue and depression and a demand for larger doses. The author did not suggest a method for management of the addiction in this case but indicated that the problem was not a minor one and that possible deleterious results from long continued use have not yet been fully investigated. He reported no change in blood pressure, but hypertensive effects from the use of amphetamine (benzedrine) have also been reported (Morse, Withrow: Effects of Benzedrine on Blood Pressure, *THE JOURNAL*, Nov. 7, 1936, p. 1582. Beyer, K. H.: *J. Pharmacol. & Exper. Therap.* 66:318 [July] 1939).

The patient with addiction to amphetamine sulfate described in the inquiry appears to have developed a tremendous tolerance to the drug and in spite of the fact that no increase in blood pressure or loss of appetite or weight has been noted he may reasonably be expected to display more of the usual reactions due to the drug as tolerance is lowered by reduction in the dosage. Dautrebande, Philippot and Charlier (Pharmacodynamic Study of Benzedrine in the Animal, *Arch. Internat. de Pharmacod. et de therap.* 62:179 [June 30] 1939) indicate that both large and small single doses produce immediate hypertension but that large doses produce hypotension when a large dose has previously been given. This suggests a possible explanation for the absence of hypertension in the case in question. A high degree of tolerance would also tend to eliminate the outward signs of stimulation of the central nervous system. The appearance of nervousness and sleeplessness on withdrawal of the drug, however, is probably the result of irritability of a nervous system long subjected to stimulation, somewhat analogous perhaps to that which occurs in opiate addiction. Rapid reduction in the number of doses rather than the size of the dose or sudden complete withdrawal is regarded as the preferred method of management of addiction to most drugs and probably causes less suffering than gradual decrease in the size of the dose. The possibility of sudden collapse must be kept in mind however and, in view of the meager information concerning the effects from prolonged use, the patient should be institutionalized to afford constant surveillance and treatment of withdrawal symptoms. Barbiturates are recognized as useful in controlling overdosage of amphetamine sulfate and may be useful together with other sedatives to control insomnia, restlessness and other symptoms of withdrawal. Care must be taken to avoid addiction to these other drugs also. The memory of the feeling of well-being or exhilaration from the psychic stimulation produced by the drug may be controlled by scopolamine hydrobromide. After the immediate symptoms of withdrawal have subsided, the principal effort should be directed to psychotherapy. In the case described, the problem of addiction apparently still persists since this has been merely transferred from alcohol to amphetamine sulfate. Unless a change in the mental attitude can be brought about the patient is likely to return to the use of stimulants of one kind or another at the first opportunity. Apparently the drug has demonstrated to the patient that he can get along without alcohol and the same now must be shown for the drug.

The Council on Pharmacy and Chemistry has recently recognized the use of amphetamine sulfate as an adjunct in the treatment of chronic alcoholism on the basis of evidence that the use of the drug in such cases may permit a sufficient interval of sobriety for the institution of the usual and more fundamental psychotherapeutic approaches (Reifenstein, E. C., Jr., and Davidoff, Eugene: The Treatment of Alcoholic Psychoses with Benzedrine Sulfate, *THE JOURNAL*, May 28, 1938, p. 1811. Bloomberg, Wilfred: *New England J. Med.* 220:129 [Jan. 26] 1939). Reifenstein and Davidoff report best results in states of intoxication in which no psychosis is demonstrable. Bloomberg points out, however, that the drug is by no means a solution of the difficult problem of alcoholism but may be useful in cases in which there can be proper supervision. Bloomberg was quoted in *Queries and Minor Notes* (Amphetamine [Benzedrine] Sulfate for Alcoholism, *THE JOURNAL*, March 11, 1939, p. 1010) to emphasize that the probable real value of the treatment lies in the opportunity it may provide to inaugurate psychotherapy so that the gain made by improved rapport, confidence and sobriety may be consolidated by the more fundamental modifications of the alcoholic addict's personality and his attitude toward life. As is also indicated in this note, the Council has repeatedly deplored the use of amphetamine sulfate except under the strict and constant supervision of the physician.

TREATMENT OF POLYCYTHEMIA VERA

To the Editor:—What can be used to reduce the blood in polycythemia vera besides phenylhydrazine hydrochloride? I am a victim of this disease and want something besides phenylhydrazine hydrochloride.

M.D., Idaho.

ANSWER:—Polycythemia rubra vera always shows an increase in total blood volume as well as an increase in red cells per cubic millimeter, so the total mass of red cells may be exceedingly high. The purpose of treatment is to dispose of this excess. Acetyl phenylhydrazine is less toxic than phenylhydrazine and is the drug of choice. The effect of the drug depends on the sensitivity of the patient and the number of red cells to be destroyed, so a set dosage cannot be followed. Usually 0.1 Gm. of acetyl phenylhydrazine can be given daily for ten days. A blood count should be done each day. With a rapid drop in cells or the development of jaundice the drug should be dis-

continued until the full effect is obtained. The amount of drug necessary to keep the count down must be determined for each patient. Often one dose (0.1 Gm.) weekly is sufficient.

Since the treatment of polycythemia rubra vera is unsatisfactory with any drug, the tendency now is to rely entirely on venesections, thus producing a relative iron deficiency anemia. Large amounts of blood must be removed. If possible the amount to be removed should be calculated from the blood volume. Most untreated patients must have from 4 to 5 liters of blood withdrawn. After venesection the red cells become smaller, so that the red cell count is not a good indicator of the effect of a need for venesections. The venesections have to be repeated at intervals of from six to twelve months.

Irradiation is a third method of treatment. It seems best to irradiate the entire body rather than the bones alone. This procedure works well for some patients and is ineffectual for others.

ALTITUDE AND CHRONIC MALARIA

To the Editor:—I read with interest the answer in *Queries and Minor Notes* July 20 under "Treatment of Chronic Malaria." The discussion parallels experience with myself and many patients. I have had chronic malaria eleven years and have taken varied forms of treatment for from two to three months each spring and fall with partial relief during the time of actually taking treatment but with no lasting results. I will not attempt to enumerate all the drugs or combinations of drugs that I have taken during the eleven years but I have used them all except the Ascoli technic and it is my understanding that this technic creates an artificial high altitude. Am I correct in this assumption? The altitude of this city is about 200 feet and I have been here eleven years except for one period of two months spent in Boston, during which time I became entirely symptom free. What altitude is considered best for becoming free from parasites under proper antimalarial treatment? One little girl aged 6 years has had malaria since birth. What routine has been found most effective in treating children of this age? I find myself entirely agreeing with your statement that the treatment of chronic malaria is not the simple task it was thought to be ten years ago.

M.D., North Carolina.

ANSWER:—The "artificial high altitude" which the Ascoli technic produces is more apparent than real. In epinephrine therapy erythrocytes are supposedly squeezed out of the blood sinuses of the spleen and other viscera and surge through the peripheral circulation in greater numbers. However, this result is fugitive, whereas normal compensation to low oxygen tension in high altitudes results in a more or less permanent increase in the hematocrit. In attempting to recover from malaria, altitude is much less important than a cool, stimulating climate, combined with a well balanced diet and moderate exercise. Thus New England, the Appalachian highlands, Minnesota and Colorado are all good climates for patients with chronic malaria. Should relapses occur in bracing climates; adequate chemotherapy is more likely to be effective there than in the warm, enervating climates of the tropics.

SUNBURN AND SULFANILAMIDE ADMINISTRATION

To the Editor:—Could you give me any available information as to whether sunburn is a contraindication to the administration of sulfanilamide?

Louis Sohn, M.D., Brooklyn.

ANSWER:—Sunburn in itself is not a contraindication to the administration of sulfanilamide or its derivatives, provided there is a good reason for using these drugs. It has been definitely established that it is unwise for a patient who is receiving one or the other of these drugs to expose himself to the direct rays of the sun during a course of treatment, because in a certain number of instances photosensitization will take place and a dermatitis will result. For this reason patients who are receiving these drugs should keep out of the sun until from two to four days after the administration of the drug has ceased. This latter precaution is recommended in order to permit the drug to be completely excreted and hence to avoid possible photosensitization.

NO CHANGE IN WASSERMANN REACTION FROM SULFANILAMIDE

To the Editor:—Can a successful Wassermann test be made on a patient with a rash due to medication with sulfanilamide?

Frank E. Wiedemann, M.D., Terre Haute, Ind.

ANSWER:—As far as evidence is available there is no reason to believe that therapy with sulfanilamide or its derivatives produces changes in or reversals of the Wassermann reaction. In the course of a large experience no difficulty has been experienced in obtaining correct interpretations of the Wassermann reaction in cases of toxic dermatoses which had been produced by the administration of sulfanilamide.

BLUISH DISCOLORATION OF GUMS

To the Editor:—A woman aged 28, single, has a bluish-purple discoloration of the upper and lower gums. This is of five days' duration. She complains of tenderness of the gums, but there has been no bleeding or ulceration. The color is homogeneously distributed, not in a line. The only other complaint she mentions is vaginal bleeding for two days following cessation of her regular period. The discoloration is only of the gums. The tongue, throat and lips are normal. Physical examination is essentially negative. The red blood cell count is 3,800,000, the white cell count 7,500; hemoglobin 78 per cent; polymorphonuclear leukocytes 62 per cent, lymphocytes 27 per cent, eosinophils 8 per cent and monocytes 3 per cent. The red cells are normal in appearance. Coagulation and bleeding times are normal, as is the clot retraction. Urinalysis is normal. The Wassermann test also is negative. There is no history of exposure to lead, mercury or bismuth, or any mouth washes or other medicines. I am unable to find the cause of her complaint and would appreciate any suggestions you may have to offer with regard to further investigation or possible etiology.

M.D., Pennsylvania.

ANSWER:—A diagnosis cannot be made from the data. A bleeding disorder in its early stages, or a disorder with bleeding as a symptom, would be suggested. Such conditions as purpura, scurvy or aleukemic leukemia are to be kept in mind. Purpura with an allergic cause has been described, and the eosinophilia would fit this possibility.

Additional information is needed, especially a platelet count. The size of the spleen is important, as is the appearance of the rectal and vaginal mucosa. (It is presumed that the patient is afebrile.)

Repetition of other examinations may be necessary. The total white blood count and differential, and the bleeding tests should be rechecked. A determination of the vitamin C level of the blood, followed by an empirical use of a vitamin C concentrate, might be done if still indicated; cutaneous tests for important allergic substances can also be done if indicated. Further therapy will depend on the condition found. At times the diagnosis may be obscure, with only a progressive anemia as its evidence.

STERILIZATION IN HEART DISEASE AND TUBERCULOSIS

To the Editor:—What reason can one give for doing a major surgical procedure (sterilization) on a woman who has tuberculosis or heart disease when a minor operation can be performed on her healthy husband? Why should one not do a bilateral ovariectomy on the husband instead of a tubal resection on a bad risk wife? I refer especially to those women who already have a child or children.

M.D., New York.

ANSWER:—As a general proposition it is probably better to perform a sterilization operation on the partner who has a disease serious enough to demand the procedure. This is especially true in diseases such as tuberculosis, which may be rather rapidly progressive and eventually kill the patient. It does not seem quite fair to sterilize a healthy young man whose wife has either a severe tuberculosis or heart disease, because at some later date he may wish to remarry and have other children.

Sterilization of women can be rapidly performed in most instances by the vaginal route with but little risk and only a short hospitalization, and with a minimum amount of trauma. If the general condition is severe, this procedure can be accomplished under morphine-scopolamine and local anesthesia in the vast majority of cases. If the vaginal procedure is not possible and laparotomy becomes necessary for tubal resection, sterilization of the man may more definitely be considered. Each case should be considered separately and judged by the age of the couple, the number of children and the financial ability to care for further children.

CHRONIC SINUSITIS AND SULFANILAMIDE

To the Editor:—Please send me whatever information regarding the status of sulfanilamides in the treatment of chronic sinus infections you have. As I am afflicted with an incurable sinus condition, the predominant organisms being *Staphylococcus aureus* and *albus*, I am wondering whether one of the sulfanilamides could be of benefit in this condition.

Charles Kantor, M.D., Summerhaven, Mount Lemmon, Ariz.

ANSWER:—Sulfanilamide and its derivatives have been used with moderate degrees of success in the treatment of acute sinusitis due to beta hemolytic streptococci, pneumococci and staphylococci. In almost all instances, however, some type of drainage has to be used concomitantly with therapy with sulfanilamide or its derivatives. In chronic sinusitis, reports on the use of sulfanilamide or its derivatives have been discouraging. The reason for the failure of sulfanilamide to benefit patients ill with chronic sinusitis probably lies in the fact that reinfection from the nasopharynx and nose is constantly taking place. Hence, while temporary chemotherapeutic effects may be obtained, the cessation of drug therapy is almost always followed by prompt recurrence of the infection in the affected sinus or sinuses.

Medical Examinations and Licensure

COMING EXAMINATIONS

BOARDS OF MEDICAL EXAMINERS

BOARDS OF EXAMINERS IN THE BASIC SCIENCES

Examination of boards of medical examiners and boards of examiners in the basic sciences were published in THE JOURNAL, October 26, page 1478.

NATIONAL BOARD OF MEDICAL EXAMINERS

NATIONAL BOARD OF MEDICAL EXAMINERS: Parts I and II. Various centers, February. Part III. Boston during November. Exec. Sec., Mr. Everett S. Elwood, 225 S. 15th St., Philadelphia.

EXAMINING BOARDS IN SPECIALTIES

AMERICAN BOARD OF ANESTHESIOLOGY: *Written*. Various centers, Feb. 20. Final date for filing application is December 21. *Oral*. Part II. Cleveland, May 31-June 1. Final date for filing application is April 1. Sec., Dr. Paul M. Wood, 745 Fifth Ave., New York.

AMERICAN BOARD OF DERMATOLOGY AND SYPHILOLOGY: *Oral*. Chicago, Dec. 6-7. Applications for Group A are closed. Sec., Dr. C. Guy Lane, 416 Marlboro St., Boston.

AMERICAN BOARD OF INTERNAL MEDICINE: *Written*. Parts I-A and I-B, Feb. 17. Final date for filing application is Jan. 1. Sec., Dr. William S. Middleton, 1301 University Ave., Madison, Wis.

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY: Part II, Groups A and B, Cleveland, May 28-June 2. Final date for filing application is March 15. Sec., Dr. Paul Titus, 1015 Highland Bldg., Pittsburgh.

AMERICAN BOARD OF OPHTHALMOLOGY: *Oral*. Cleveland, May or June. *Written*. Various centers, March 8. The only written examination during 1941. Applications must be on file not later than Dec. 1. Sec., Dr. John Green, 6830 Waterman Ave., St. Louis.

AMERICAN BOARD OF ORTHOPAEDIC SURGERY: *Oral and written*. New Orleans, January 1941. Final date for filing application is November 15. Sec., Dr. Fremont A. Chandler, 6 N. Michigan Ave., Chicago.

AMERICAN BOARD OF PATHOLOGY: *Oral and Written*. Cleveland, June 1-2. Final date for filing application is May 1. Sec., Dr. F. W. Hartman, Henry Ford Hospital, Detroit.

AMERICAN BOARD OF PEDIATRICS: New York, March 30-31, following the Region I meeting of the American Academy of Pediatrics. Chicago, May 18, following the Region III meeting of the American Academy of Pediatrics. Sec., Dr. C. A. Aldrich, 723 Elm St., Winnetka, Ill.

AMERICAN BOARD OF UROLOGY: *Oral and Written*. All groups. Chicago, Feb. 14-16. Final date for filing application is Nov. 10. Sec. Dr. Gilbert J. Thomas, 1009 Nicollet Ave., Minneapolis.

North Carolina June Report

Dr. W. D. James, secretary, Board of Medical Examiners of North Carolina, reports the written examination for medical licensure held at Raleigh, June 17-21, 1940. The examination covered sixteen subjects and included seventy questions. An average of 80 per cent was required to pass. Sixty-five candidates were examined, all of whom passed. Thirty-four physicians were licensed to practice medicine by reciprocity and nine physicians so licensed by endorsement. The following schools were represented:

School	PASSED	Year Grad.	Per Cent

Care of Poliomyelitis. By Jessie L. Stevenson, A.B., R.N., Consultant in Orthopedic Nursing, National Organization for Public Health Nursing. Cloth. Price, \$2.50. Pp. 230, with illustrations. New York: Macmillan Company, 1940.

This book is timely, practical and accurate. It is written by a nurse who has demonstrated mature, discriminating judgment. Miss Stevenson has presented an unbiased evaluation of various conceptions, procedures, maneuvers and methods. The book has grown out of the study, observation and experience of the staff of the orthopedic division of the Visiting Nurse Association of Chicago. It is presented in the hope that it will be useful to others who share in the care of poliomyelitis patients. The manuscript has been read in whole or in part by instructors, supervisors and staff nurses in public health nursing, instructors in physical therapy departments, and directors and members of staffs of state agencies for the care of crippled children. The value of care in handling the acutely ill patient is emphasized. The discussion on postural considerations is excellent. The author has taken meticulous care in describing the simplest details. These include the value of serum, the incomplete or complete arc movement and underwater exercises. The author was careful in choosing her source material and was accurate in quoting and paraphrasing the writings and teachings of her predecessors. The references are valuable. Many personal experiences are interspersed. Dr. Hektoen considers the description of the nature, the virus, the apparent modes of spread, the structural changes, the course of the attack, the treatment of the acute stage and the period of recovery of poliomyelitis to be in full accord with the present understanding and teaching of the disease. The author provides a sound and substantial basis for an intelligent grasp of the principles of the convalescent care, early and late, explained with a mastery of detail. Miss Deming of the National Organization for Public Health Nursing states that "public health nurses will welcome this book. Stevenson is an authority on the subject of orthopedic nursing. The book will be particularly helpful to those public health nurses in the field who are responsible for supervising the care which the family gives the victims of poliomyelitis. Many of the instructions are applicable also to other types of crippling conditions as well as poliomyelitis. The book is full of practical examples of how to administer care and includes many teaching points. It is also very well illustrated. Our home teaching very much needs this type of instruction and guidance. The book, therefore, will be doubly welcome to the supervisors and instructors of public health nurses."

Dermatologic Therapy in General Practice. By Marlon B. Sulzberger, M.D., Assistant Clinical Professor of Dermatology and Syphilology, Skin and Cancer Unit of the New York Post-Graduate Medical School and Hospital of Columbia University, New York, and Jack Wolf, M.D., Attending Dermatologist and Syphilologist, Skin and Cancer Unit of the New York Post-Graduate Medical School and Hospital of Columbia University. Cloth. Price, \$4.50. Pp. 680, with 65 illustrations. Chicago: Year Book Publishers, Inc., 1940.

This work, like most of Sulzberger's "practical utterances," is a painstaking attempt to present to the general practitioner a book on the management of the common skin diseases that the authors "hope will prove useful to the general practitioner." Little mention is made "of many details of morphology or of differential diagnostic finesse." The authors are to be commended for only lightly mentioning roentgen and radium therapy because these agents are used too frequently by "x-ray specialists" and laboratory technicians without proper special diagnostic training. The work describes many practical procedures for the management of skin diseases in greater detail than found in the usual comprehensive textbook, and much material has been taken from previous writings in the Year Book and medical journals and Sulzberger's wide contact with therapy in his own practice and from contact with his preceptors in continental Europe. The details of dermatologic therapy are well presented. In addition to complex therapy, dermatology has a complex diagnostic approach and the reviewer feels that the authors allocate to the average general practitioner a knowledge in properly classifying skin diseases that they do not ordinarily possess. For therapeutic reference

it is essential that they know the entity for which they are prescribing or seeking management advice. The general practitioner who is secure in his diagnosis of a wart or psoriasis will find in this work a number of therapeutic suggestions but will have to decide for himself which treatment to use. The following statement in the section on senile pruritus on page 546 is a highlight of ambiguity: "The condition is usually easily managed, but in some cases proves particularly rebellious to treatment." Chapter XIII, on drug eruptions, is superbly done. Table 14 on page 552, listing common drugs causing eruptions and characteristic forms of eruptions, is excellent and should be of great value to the practitioner in running down drugs as a causal factor in an eruption. This book should prove of great value to the erudite practitioner who has still retained some of his cutaneous diagnostic orientation and desires aid in therapeutic approach and should also be of great value to the novice in dermatology with a restricted therapeutic horizon. It is a valuable practical addition to the dermatologist's library and to that of the general practitioner who desires to treat dermatologic conditions with more armaments than calamine lotion and sulfur and Whitfield ointments. Chapters XV and XVI, on syphilis, are superbly done and should be read and reread by the general practitioner.

Pneumoconiosis Among Mica and Pegmatite Workers. By Waldemar C. Dressen, Passed Assistant Surgeon, United States Public Health Service, and others. From the Division of Industrial Hygiene, National Institute of Health. Prepared by direction of the Surgeon General. Federal Security Agency, U. S. Public Health Service. Public Health Bulletin No. 250. Paper. Price, 15 cents. Pp. 74, with 30 illustrations. Washington, D. C.: Supt. of Doc., Government Printing Office, 1940.

The report includes (1) detailed descriptions of the process of mining and quarrying pegmatite rock, the milling of its major constituents, mica, feldspar and quartz, with a section on hydraulic mining and processing of kaolin; (2) the concentration of atmospheric dusts generated in these different processes; (3) complete medical data obtained from examining fifty-seven men exposed to fine silica-free mica dust, thirty-one men and seventy-eight women fabricators of sheet mica, ninety-five men exposed to kaolin dust, 741 men mining the pegmatite and sorting its chief constituents, and a control group of 245 applicants for work who had had no previous exposure to dust.

For details of this carefully conducted study one must consult the original paper. The chief conclusions of the report were that the inhalation of fine mica dust generated in grinding this material caused a pneumoconiosis demonstrable clinically and by x-ray examination, that the fabrication of sheet mica did not liberate enough dust to produce demonstrable pulmonary changes, that mining pegmatite rock under conditions in which dust was generated in concentrations in excess of ten million particles per cubic foot of air would produce typical silicosis after a sufficient period of exposure and that with higher concentrations of dust the probabilities of developing silicosis in a shorter time were even greater. "No appraisal of the pneumoconiosis-producing potentialities of kaolin can be made at this time on the basis of examinations of ninety-five men exposed to practically pure kaolin dust, because only ten men had been exposed to dust concentrations in excess of ten million particles per cubic foot for as long as ten years." Likewise the influence of feldspar could not be evaluated, as this substance was milled in the same building as the quartz, where men were exposed to dusts of both substances. In such mills 8.3 per cent of the men exposed had developed silicosis, whereas in the mine and quarry group only 2.7 per cent showed evidence of such change. The incidence of associated tuberculosis in the whole group was low. Among the total of 1,243 men and women examined there were only six cases of presumptively active infection (0.48 per cent), and of these two were confirmed by subsequent study. This low incidence closely corresponded with that in nearby counties where no mining was carried on. In this connection there is an interesting discussion of the epidemiologic phases of the problem.

The treatment of the subject is somewhat confusing, owing to the variety of minerals under discussion and the implication that each one of them is capable of producing similar pathologic changes and clinical symptoms. Although one section of the report specifically states that the miners exposed to dust containing quartz develop silicosis while the mica millers, breathing

quartz-free dust, are subject only to pneumoconiosis, nevertheless in other places the term pneumoconiosis is used generically to include silicosis. To the reviewer the Public Health Service's scheme for classifying the x-ray shadows produced by reaction to inhaled dusts is a misdirected attempt at simplification. It includes in a single classification shadow patterns produced by three distinct types of pathologic reaction that are provoked by different kinds of minerals. The scheme implies that any form of pneumoconiosis will progress from linear exaggeration through the granular stage to one of nodulation. Pathologically the benign, nonspecific types of pneumoconiosis that have thus far been studied are characterized by linear deposits of dust about the vascular trunks and interlobular septums, asbestosis by a fine diffuse fibrosis involving the alveolar septums, and silicosis by nodules of fibrosis throughout the parenchyma. There is no tendency for one form to pass over into the other.

The report states that this mica pneumoconiosis whose x-ray manifestations resemble those of asbestosis has not been studied pathologically. Since so little is known about this condition, one wishes that its symptoms and physical signs had been tabulated instead of being dismissed with the statement that they "did not differ in nature or in incidence from the symptoms and signs of silicosis." An appendix details the results of animal injections with the mica, kaolin, feldspar and quartz involved in these industries. Intraperitoneal injections of all but the quartz caused "inert" reactions, a type which they "have interpreted as being potentially harmful and capable of producing a diffuse interstitial pulmonary fibrosis as does asbestos." Personal experience with this and other animal tests raises doubts in the reviewer's mind as to the validity of this generalization. Some feldspars with which he has worked have proved incapable of causing any significant tissue reactions. The micas, on the other hand, seem to be more irritating and cause a limited amount of chronic inflammation, particularly in the case of the black mica biotite. They have not been tested in animals' lungs. It is to be hoped that necropsy material from human beings with prolonged exposures to mica dust may be obtained to furnish a basis for the x-ray manifestations of the pneumoconiosis reported.

Meditsinskaya literatura SSSR. Ukazatel knig i statey zhurnalov i sbornikov 1936. God izdaniya shestoy. [Medical Literature of Russia: Index of Books and Articles, Journals and Pamphlets for 1936. Sixth Year of Issue.] Cloth. Price, 50 rubles. Pp. 754. Moscow & Leningrad: Gosudarstvennoe Izdatelstvo Meditsinskoy Literatury, 1939.

The volume is the Russian index medicus for 1936. It lists only Russian publications. The present is the sixth annual volume. The material is catalogued under subject headings and their subdivisions in alphabetical order. There is an authors' index at the end. The size of the volume speaks well for the literature output. When a 1936 index makes its first appearance in 1939, its value to the clinician and the research worker is somewhat questionable. Just what the advantage is of bringing out an index limited to the Russian literature is not quite clear. Methodology has never been a strong point with the Russians. The reviewer's opinion is that our Russian colleagues could learn much by careful perusal of the *Quarterly Cumulative Index Medicus*.

New and Nonofficial Remedies, 1940. Containing Descriptions of the Articles Which Stand Accepted by the Council on Pharmacy and Chemistry of the American Medical Association on January 1, 1940. Cloth. Price, \$1.50. Pp. 656. Chicago: American Medical Association, 1940.

The most important function of this book, and of the Council on Pharmacy and Chemistry, of whose deliberations it is the result, is to place before the medical profession a description and estimate of new and useful medicinal preparations as they become available. Even after preparations become official, many brands are retained in New and Nonofficial Remedies by the desire of the manufacturers, who appreciate the care given by the Council in acceptance.

The present volume again reflects contemporary advances in chemotherapy by the inclusion of Sulfapyridine, a derivative of Sulfanilamide which was admitted last year; Sobisminol Mass and Sobisminol Solution, new bismuth compounds, the former having been found efficacious in the oral treatment of syphilis; Fuadin, an antimony derivative which has been known for some years but only recently accepted by the Council for use in the

treatment of venereal granuloma and bilharziasis. Other new admissions are Pentothal Sodium, a barbiturate of brief and effective action; Racéphedrine with its hydrochloride and sulfate, which as its name indicates is the racemic form of ephedrine; Mercupurin, Salyrgan and Salyrgan-Theophylline solution, mercurials which are used as diuretics.

A glance at the preface shows that some textual revisions are included in the new volume and that a number of products have been omitted as being off the market or as being in conflict with the Council's rules. Noteworthy revisions are those of the chapter on Liver and Stomach Preparations, radically rewritten and including a statement of requirements suggested by conclusions of the Anti-Anemia Preparations Advisory Board of the U. S. Pharmacopeia; the subsection Tuberculins, entirely rewritten to conform to newer knowledge in this field, and the chapter Allergenic Protein Preparations, the name of which has been changed to Allergenic Preparations. Minor but relatively important revisions are found in the articles Bismuth Compounds, Serums and Vaccines, and Vitamins and Vitamin Preparations for Prophylactic and Therapeutic Use.

The book is recommended for all physicians and for all interested in the uses, production or evaluation of drugs.

Clinical Practice in Infectious Diseases for Students, Practitioners and Medical Officers. By E. H. R. Harries, M.D., M.R.C.P., D.P.H., Medical Superintendent, North-Eastern Hospital (London County Council), London, and M. Miltman, M.D., M.R.C.P., D.P.H., Medical Superintendent, River Hospitals, Orchard Dartford, Kent. With a foreword by W. Allen Daley, M.D., F.R.C.P., D.P.H., Medical Officer of Health, London County Council, London. Cloth. Price, \$6. Pp. 468, with 31 illustrations. Baltimore: William Wood & Company, 1940.

The authors discuss the clinical aspects of the acute infectious diseases based largely on their own experience as clinicians and teachers; they also discuss the modern fever practice as reflected in the work of others. The opening chapters deal with the sources of infection, resistance to infection, laboratory aids and clinical tests in diagnosis, general management and diet. The student should master this part before proceeding to the chapters on the treatment of the individual infectious diseases, including those that are likely to assume great importance under war conditions, such as epidemic typhus, influenza, tetanus, trench fever and Weil's disease. Prophylaxis is emphasized. While the book is an elaboration of notes on clinical lectures delivered to medical students in London, it provides an account of the clinical aspects of infectious diseases in sufficient detail to be a great help to practitioners of medicine and public health officers in the management of these conditions.

Regional Differences in the Hospitalization and Care of Patients with Mental Diseases. By Joseph Zubin and Grace C. Scholz, United States Public Health Service Associated with the Mental Hospital Survey Committee. Federal Security Agency, United States Public Health Service. Division of Sanitary Reports and Statistics. Supplement No. 159 to the Public Health Reports. Paper. Price, 15 cents. Pp. 94. Washington, D. C.: Supt. of Doc., Government Printing Office, 1940.

The 416,784 patients with mental diseases in hospitals occupy more than 50 per cent of all the hospital beds in the United States and account for almost one fifth of the expenditures in all hospitals. There were 328 individuals in every hundred thousand of the general population in mental hospitals during 1935. The rate in New England was 449 per hundred thousand while in the East South Central region it was less than half as much, or only 206.

This difference probably reflects lack of facilities rather than difference in the prevalence of mental disease. Ninety-seven per cent of the patients are diagnosed as "with psychosis." The higher percentage of patients "without psychosis" in some states is due to the lack of facilities for the mentally deficient and the epileptic. Mental diseases are primarily a governmental burden, more than 95 per cent of all patients being cared for in governmentally controlled institutions. In accordance with the change in population age groups, the number of first admissions below 50 years of age is decreasing while above that age it is increasing. For the entire country there is an overcrowding of hospitals for mental diseases of 11.4 per cent, but this rate varies largely, being highest in the Pacific region with 23.6 per cent.

Inadequacy of personnel is even more striking. The American Psychiatric Association sets a standard of one physician to 150 patients. There were in 1935 one physician for 258.6 patients, and in the East South Central district the ratio was 445.6

patients per physician. The nursing situation is nearly as bad. To meet the standard of the American Psychiatric Association of one nurse to eight patients there is a need for 10,500 more nurses. Only 11 per cent of the present nursing staff consists of graduate nurses.

The cost of caring for the mentally diseased is more than \$230,000,000 annually, or an average expenditure of \$534.25 per patient. There is little reason to believe that the geographic differences are as important as the administrative and environmental factors.

Shell Shock in France 1914-18 Based on a War Diary. Kept by Charles S. Myers, C.B.E., F.R.S., Temporary Lieutenant-Colonel, Royal Army Medical Corps. Cloth. Price, \$1.25. Pp. 146. Cambridge: University Press; New York: Macmillan Company, 1940.

During the World War Dr. Charles S. Myers was consulting psychologist to the British armies in France. This book is based on his war diary and deals particularly with cases of shell shock and with reeducation. Apparently many cases of a disturbance still called shell shock are occurring in the present war, amplified indeed by the discovery of new weapons more terrifying than any available in 1918. The volume is of special interest, of course, to British physicians but it also provides much that is interesting and useful to physicians everywhere. It is the mark of an intelligent man to learn by his and others' mistakes. Dr. Myers has found even the recollection of many of the errors of 1914-1918 an exceedingly painful performance.

Archiv und Atlas der normalen und pathologischen Anatomie in typischen Röntgenbildern. Atlas des Röntgenreihenbildes des Brusttraumas auf Grund der Auswertung von über 900000 Röntgenreihenschirmbildern. Zusammenestellt von Hans Holfelder und Friedrich Berner. Fortschritte auf dem Gebiete der Röntgenstrahlen, Ergänzungsband LXI. Herausgegeben von Prof. Dr. Grashey. Paper. Price, 17.50 marks. Pp. 95, with 244 illustrations. Leipzig: Georg Thieme, 1939.

Since the beginning of roentgenology, many attempts have been made to make ordinary photographs of the fluoroscopic screen image. Many difficulties have, until recently, prevented the successful development of this idea. Manoel de Abreu of Rio de Janeiro was probably the first (1936) to make practical application of such a method in a chest survey of large numbers of individuals. The present authors, like de Abreu, have used a 35 mm. camera. A rapid lens and firm mounting of the camera in relation to the screen are prime necessities. The wealth of material represented by a survey of more than 900,000 individuals is exemplified in the atlas. Early tuberculosis was recognized in numerous cases. There is no doubt about the value of miniature camera serial photography of the fluoroscopic screen image as far as concerns case finding or survey studies in pulmonary disease. A special instrument fitted with a magnifying glass serves for rapidly passing the films before the examiner. Such a device is always necessary if one uses such small films. The tendency in the United States is to use a larger film, one about 4 by 5 inches in size, which is still small enough to make real economy in its use and yet large enough to be readily interpreted without enlargement, or at least no greater enlargement than that provided by a simple reading glass.

Pratique médico-chirurgicale. Publiée sous la direction de A. Couvélaire, A. Lémierre, et Ch. Lenormant, professeurs à la Faculté de médecine de Paris. Secrétaire général: André Ravina. Tome X, Deuxième supplément. Third edition. Half-cloth. Price, \$5.25. Pp. 671, with 233 illustrations. Paris: Masson & Cie, 1939.

This volume is the second supplement to an eight volume system of the Practice of Medicine and Surgery published in 1931. The first supplement was published in 1936. A wide range of material in all fields of therapy and diagnosis is covered. An index of the scope of the book is given by a few titles: carotid sinus surgery, ski accidents, sulfonamide drugs, pelvic measurements, surgical treatment of tuberculosis, electroencephalograms, treatment of megacolon, cardiac surgery. The illustrations throughout the book are excellent. The treatment of the subject matter differs somewhat in emphasis from the American literature; for example, there is a longer section on ski accidents than on the sulfonamide drugs. However, there is at least brief mention of the most important changes in medical practice to the date of publication. This book should prove a useful compendium and almanac to any one able to read French.

Behind the Scenes of Murder. By Joseph Catton, M.D., Clinical Professor of Medicine, Stanford University, San Francisco. Cloth. Price, \$3. Pp. 355. New York: W. W. Norton & Company, Inc., 1940.

This volume results from twenty-seven years of practice in psychiatry, which incidentally gave the author opportunity to act as an expert in such famous cases as those of Winnie Ruth Judd, William Hickman and the famous Massie case in Honolulu. Not only does he provide evidence in support of his views from a considerable number of instances of murder in which he acted as either investigator or witness, but also he makes out of medical testimony and his participation an exceedingly dramatic and excellent literary document. One chapter refers to his clash with Clarence Darrow in the Massie case and throws an extraordinary light on the Darrow methods and technic. This is an important contribution to modern scientific criminology and at the same time one of the most interesting works that have been developed in its field.

Le traitement actuel de la tuberculose pulmonaire. Par P. Weiller, assistant à l'Hôpital Beaujon, et S. Katz, assistant libre à l'Hôpital Beaujon. Préface par le Dr Louis Ramond, médecin de l'Hôpital Laënnec. Paper. Price, 90 francs. Pp. 234, with 57 illustrations. Paris: Vigot Frères, 1940.

This well illustrated booklet is written for the general practitioner. The forms and types of tuberculosis are classified according to practical considerations. Factors in diagnosis, including instructive x-ray reproductions and evaluation of laboratory aids, are intelligently discussed. The indications and contraindications for surgical treatment are dwelt on. Sufficient space is devoted to the discussion of chemotherapy, vaccine therapy, dietetic management and change in environment. The problems of smoking, drinking, sex life and marriage are freely discussed. Special chapters are devoted to tuberculosis in the infant and the aged. The style is clear and simple, and the book will be an asset to the library of the general practitioner.

Archiv und Atlas der normalen und pathologischen Anatomie in typischen Röntgenbildern. Differentialdiagnostik der Lungenerkrankungen im Röntgenbilde unter besonderer Berücksichtigung der Queraufnahme. Von Dr. med. habil. O. Simon, Leiter der Röntgen-Abteilung der Medizinischen Universitätsklinik Königsberg i. Pr. Fortschritte auf dem Gebiete der Röntgenstrahlen, Ergänzungsband LVII. Herausgeber: Prof. Dr. Grashey. Paper. Price, 17 marks. Pp. 84, with 204 illustrations. Leipzig: Georg Thieme, 1939.

The first half of the work is devoted to text, the latter half consisting of excellent illustrations. In nearly every instance the author shows the anteroposterior film as well as the lateral, thus facilitating the comparison of the two projections. Any one not already convinced of the value of the lateral film in thoracic roentgenology would do well to study this atlas. It is brimful of interesting cases, some of which would not have been diagnosed except with the aid of the lateral film.

Obesity and Leanness. By Hugo R. Rony, M.D. Cloth. Price, \$3.75. Pp. 300, with 32 illustrations. Philadelphia: Lea & Febiger, 1940.

Here, planned particularly for the general practitioner, is a scientific discussion of obesity and leanness. Many a practitioner today is confronted by representatives of each of these groups anxious to transfer to the other. Scientific control of either obesity or leanness demands a thorough understanding of the physiology and pathology of fat, of the physiology of hunger, and of rest. Dr. Rony inclines to the concept of physiologic bookkeeping with, of course, a recognition of pathologic studies in which the glands have failed to function. The third portion of the book is wholly clinical. It considers indications and contraindications for reduction of weight and also for the use of thyroid glandular material and other methods in controlling and maintaining weight.

A Man Who Found a Country. By Dr. A. Nakashian. Cloth. Price, \$2.75. Pp. 279, with illustrations. New York: Thomas Y. Crowell Company, 1940.

Dr. Nakashian was born in a Turkish town but he is an Armenian. His life reflects first hand the constant difficulties of Armenians with Turks and the place that the American missionaries occupied, particularly in aiding the Armenians. He graduated from the American College in 1887 and decided to take up medicine. He describes how it was necessary to purloin corpses in order to secure material for dissection. Briefly, he became a soldier and learned Arabic. In 1894 he received a

degree in medicine; he then went for further study to Constantinople. Here he began medical practice under difficult conditions. Like many a physician of earlier days he moved toward success by surgery on the governor. After becoming a captain in the Turkish army, being drafted into military service, he became physician to a bandit chief. His story ends with his departure for America. The story is a simple, first hand account of an extraordinary medical career.

Sex Adjustments of Young Men. By Lester A. Kirkendall, Ph.D., Associate Professor of Education, Teachers College of Connecticut, New Britain, Conn. Foreword by Percival M. Symonds. Cloth. Price, \$2. Pp. 215. New York & London: Harper & Brothers, 1940.

The book is the result of twelve years of counseling work with boys and young men. He describes in detail with adequate documentation commonly found forms of sex adjustment among young men, commonly held misconceptions concerning sex and certain histories of actual case histories of difficulties of adjustment among young men. This material is well worth study by psychiatrists working with college students or adolescents. Disappointment with the chapter dealing with desirable sex adjustments will be felt by all psychiatrists engaged in therapy. Among thirteen precepts to be followed are Do not be disturbed by manifestations of sex, Do not toy with sex or put yourself in the way of stimulation, Plan how you will meet difficult situations before they arise and Adopt an attitude that is direct, objective, free from lewdness and obscenity. Perhaps it is too much to hope that a college professor should have a realistic attitude toward life, but surely some inkling of man's terrific struggle against his instincts should by now have permeated to teachers of education.

Bureau of Legal Medicine and Legislation

MEDICOLEGAL ABSTRACTS

Hospitals: Liability for Failure to Place Sideboards on Patient's Bed.—Mrs. Potter was admitted to the defendant hospital Thursday, February 16, in a very restless and nervous state. At times she was irrational. A special nurse was employed to attend her during the night and was retained through the following Sunday night, February 19. Sideboards were placed on the patient's bed the first night of her stay in the hospital but were not used thereafter. On Monday the special nurse was dismissed on the advice of the defendant's supervisor of nurses, who thought further employment unnecessary because the patient "apparently was rational and was so much quieter." About midnight Monday a student nurse visited the patient's room and found her "quiet and rational," but on her return about five minutes later she found Mrs. Potter sitting on the edge of the bed with her legs and feet dangling, apparently preparing to leave her bed to go to the bathroom. The patient fell but the nurse caught her by the shoulders. The patient fractured her femur in the fall and two days later died of pneumonia. The surviving husband and children of the patient sued the hospital, contending that her death had been proximately caused by the fall, which in turn was the result of the hospital's negligence in not placing sideboards on the patient's bed the night of the fall. At the close of the evidence the trial court refused to direct a verdict in favor of the hospital and entered judgment for the plaintiffs on the verdict of the jury. The hospital then appealed to the Supreme Court of Idaho.

The theory of the plaintiffs' claim, said the Supreme Court, is that, since sideboards were placed on the patient's bed the first night she was in the hospital and since none were on her bed the night of the fall, the hospital was negligent in not placing sideboards on the bed the latter night and that such negligent omission resulted in her fall and injury. The plaintiffs contended that the patient's condition was such on the night of the fall that the hospital attendants should have known that she might become irrational at any moment or that she might be expected to try to get out of bed. But, answered

the Supreme Court, the uncontradicted testimony of the student nurse is that five minutes before the fall the patient was conscious and was resting quietly. The record shows that the patient had been quiet during the daytime on Monday and there is no evidence to show that the hospital could or should have inferred that the patient on the night of the fall would conduct herself differently from other patients who were "resting quietly." Surely a hospital is not bound to place sideboards on the bed of every patient. One of the defendant's nurse supervisors testified that in her opinion there is no need for the use of sideboards when a patient is in a condition such as Mrs. Potter was in on Monday. Moreover, there was testimony that the use of sideboards for conscious patients may even be bad therapy since such patients can, and often do, crawl over sideboards, and any resulting fall, occurring as it does from a greater height, is likely to have more serious consequences. In the opinion of the court, there was no evidence to show that in not attaching sideboards to the patient's bed the hospital had failed to exercise due care prior to and at the time of her injury. The mere fact that a sideboard was placed on the patient's bed immediately after her fall did not justify an inference that due care required the hospital to put on sideboards before the fall. After the fall the hospital was confronted with a different situation because the patient had become very restless and was in pain. Her condition had changed, and so a different standard of due care may then have been required than was required prior to the fall.

In view of the testimony above, said the court, even under an assumption that Mrs. Potter involuntarily rolled from her bed, the plaintiffs failed to prove negligence on the part of the hospital. But, continued the court, the hospital's defense was even stronger. Even if it be conceded that sideboards would have prevented the patient from involuntarily rolling from her bed, there was positive and uncontradicted testimony that at the time of her fall Mrs. Potter did not involuntarily roll from her bed but rather she was making a conscious and voluntary effort to leave her bed to go to the bathroom. It would seem, therefore, that the patient's fall and injury resulted from her own voluntary and conscious action and not from any negligent act of omission or commission on the part of the hospital.

Since there was no evidence to establish negligence on the part of the hospital, the Supreme Court held that the trial court should have directed a verdict for the hospital, and so it reversed the judgment in favor of the plaintiffs.—*Potter v. Dr. W. H. Groves Latter-Day Saints Hospital (Utah)*, 103 P. (2d) 280.

Dental Practice Act (California): Self-Laudatory Advertising Not Unprofessional Conduct.—The appellant, Webster, who was licensed to practice dentistry in California, ran an advertisement in a newspaper praising the excellence of the "immediate restoration dentures," which he prepared for patients by "The Webster Way." These dentures, so the advertisement stated, were made according to a secret formula from "the newest plate material in dentistry," and they enabled the patient to have a "natural expression" which "defied detection" from any one. The advertisement in general stressed Webster's painstaking care, his skill and his success in this particular field of dentistry. On the ground that by running this advertisement Webster was guilty of unprofessional conduct in that (1) he had advertised professional superiority or the performance of professional services in a superior manner, (2) he had made use of advertising statements of a character tending to deceive the public and (3) he had advertised to guarantee dental services (any of which allegations, if proved, was sufficient cause for revocation of a license to practice dentistry under the California dental practice act), the Board of Dental Examiners suspended his license. Webster appealed to the courts and the matter eventually reached the district court of appeals, fourth district, California.

The question involved in this case, said the district court, is one of ethics, on which professional men have honest differences of opinion. But this court cannot determine ethical questions. It can determine only whether or not there has been a violation of the California dental practice act. In 1935, the California legislature joined other states in a movement to

make dentistry a more dignified and ethical profession and accordingly passed legislation regulating dental advertisements. The law so enacted in California, however, does not prohibit advertising entirely, as was done in some states, but sets up "some standard to regulate a limited form of advertising." There has been a marked tendency in recent years to enact more stringent regulations concerning the practice of law, medicine and dentistry, designed to protect the ignorant, gullible members of the public from quacks and charlatans, who spurn the ethics of their profession and thrive on ornate methods of advertising. However that may be, a statutory proceeding for the revocation of a license is in the nature of a criminal trial in which all intendments are in favor of the accused. In the absence of evidence that there has been violation of the law, the presumption is that the law has been obeyed.

We cannot here, continued the court, analyze each statement in the advertisement complained of. Some of the statements, when separately stated and technically construed, together with the inferences that may be drawn from them, may border on a violation of the dental practice act. However, it must be remembered that the truth of the statements set forth in the advertisement was not challenged by the board of dental examiners. Therefore, it can hardly be maintained (1) that they were of a character tending to deceive or mislead the public or (2) that they advertised a professional superiority or the performance of professional services in a superior manner or (3) that the advertisement was to guarantee any dental service. While we do not wish to condone any attempt to circumvent the spirit and intent of the law and open the field to quacks and charlatans, in view of the fact that disciplinary proceedings are of a criminal nature and that a license to practice dentistry is a property right of which the holder cannot be arbitrarily deprived, we must hold that the board of dental examiners has not met the burden imposed on it to establish by clear and convincing evidence the accused dentist's guilt, which must be done before his license to practice dentistry can be revoked or suspended.

The district court of appeals accordingly directed the board of dental examiners to reinstate the dentist's license to practice.—*Webster v. Board of Dental Examiners of California* (Calif.), 103 P. (2d) 442.

Malpractice: Liability of Hospital Association as Affected by Judgment for Professional Employee.—The plaintiff entered into a contract with the Industrial Hospital Association by which the latter, in consideration of a certain fee to be paid to it monthly, agreed to provide him with hospital, medical and dental services if and when necessary. Later it became necessary to extract one of the plaintiff's wisdom teeth and the Hospital Association directed him to go to Dr. Roberts, a dentist, who extracted the tooth. Infection which followed the extraction was due, the plaintiff alleged, to the dentist's negligence, and he sued both the Hospital Association and the dentist. At the conclusion of the plaintiff's evidence the trial court dismissed the suit as to the Hospital Association and later the jury returned a verdict in favor of the dentist, thereby, as the Supreme Court of Oregon said on appeal, "exonerating him [the dentist] from the charge of negligence." The trial court subsequently ordered a new trial as to the Hospital Association but not as to the dentist, and the Hospital Association appealed to the Supreme Court of Oregon.

The Hospital Association contended that the dentist was an independent contractor and that it had performed its obligations under the contract when it exercised due care in the selection of a dentist to render service to the plaintiff. The plaintiff contended that the dentist was an agent of the association and that the association was responsible for the dentist's negligence. Assuming, said the Supreme Court of Oregon, that the doctrine of respondent superior applies, we are of the opinion that the verdict exonerating the dentist from the charge of negligence precludes recovery against the principal, the Hospital Association. The Hospital Association and the dentist were not joint tort-feasors. There was no independent act of negligence charged against the Hospital Association. If it is liable it can be so only by reason of the negligence of its agent, the dentist. When the judgment was rendered in favor of the dentist—from

which there has been no appeal by the plaintiff—the foundation of any case against the association was destroyed. If the case were to be retried it would be incumbent on the plaintiff to show negligence on the part of the dentist, and that matter has been adjudicated adversely to the plaintiff's contention. The court then quoted from 2 American Jurisprudence 361, reading in part as follows:

... where the tortious liability of the principal is based solely upon the act of his agent with whom he is being sued, a verdict in favor of the agent necessarily amounts to a finding that the principal also is not liable.

The Supreme Court accordingly reversed the order of the trial court granting a new trial as to the Hospital Association and ordered the trial court to reinstate the judgment of dismissal as to the association.—*Feazle v. Industrial Hospital Ass'n* (Ore.), 103 P. (2d) 300.

Dental Practice Acts: Statutory Restrictions on Advertising Upheld.—The dental practice act of Kentucky, enacted in 1938, provides that the state board of dental examiners may revoke a dentist's license for "unprofessional conduct." Certain activities are specified in the act as constituting "unprofessional conduct," among which is "advertising credit or terms of credit" extended by the practitioner to his patients. The plaintiff, a practicing dentist in Kentucky, filed a petition for a declaratory judgment to determine the validity of this provision in the dental practice act prohibiting "advertising credit or terms of credit." He contended that the prohibition against such advertising violated his constitutional rights under the state and federal constitutions. From a judgment sustaining the demurrer of the state board of dental examiners the plaintiff appealed to the Court of Appeals of Kentucky.

It was conceded, said the Court of Appeals, that the profession of dentistry and its practice are subject to the police power of the state and that the exercise of that power must be reasonable. Therefore, the only question before the court was whether or not the provision of the Kentucky dental practice act in question, which was enacted under the police power, reasonably affected or promoted public health, morals, safety or general welfare. In the opinion of the court it did. All dentists as well as physicians and members of other professions are not of equal capacity and the selection of the particular professional man to treat or represent the individual may, under the police power of the state, be regulated by considerations other than those purely economical. Persons of modest financial means and persons suffering from bodily ills are frequently not in a position to judge competently between the ability of different practitioners. Clearly, then, it was within the province of the exercise of the police power for the legislature to forbid any attempt to influence the public generally in the selection of a dentist through the medium of advertisements of credit and credit terms. The court was unable to differentiate between the damaging effects of advertising through paid agents and advertising by any other means through which patients, who perhaps would not have come but for the advertisement, are drawn to the office of the advertiser. The validity, said the court, of statutes prohibiting members of the dental profession from advertising for patrons in any form has been questioned frequently, but in every such instance the constitutionality of the statute has been upheld. While the court was unable to find a prior court decision involving a statute which specifically prohibited "advertisement of credit and terms of credit," in its judgment the same principles of law announced in the cases relating to prohibition of advertising in general by professional persons were applicable to the instant case, because "advertising credit or terms of credit" is nothing more nor less than an effort by which the practitioner seeks to bring patrons to his office through the advertised inducement of credit, on enticing and satisfactory terms.

The whole structure of the law in upholding legislation regulating the practice of members of any branch of the medical profession is based on the theory that a practitioner should not engage in any conduct smacking of quackery but should let his work prove and establish his worth, instead of "blowing his own horn" in an effort to bring about that establishment. Patients should seek the physician or dentist because of his capability, and not the physician or dentist obtain patients through their gullibility. The purpose of the legislature in

enacting the provision in question was, in effect, to prevent undue solicitation by dentists based on a financial appeal and to maintain a proper dignity and standard of professional practice in dentistry. These were clearly matters looking to the promotion of public health and general welfare. The authority so exercised by the legislature was the quintessence of police power, and no occasion speaks louder for its exercise and application than the proper regulation of those engaged in the delicate task of tinkering with the human body.

Accordingly, the judgment of the lower court upholding the constitutionality of the Kentucky dental practice act was affirmed. —*Reynolds v. Walz et al. (Ky.)*, 128 S. W. (2d) 734.

Privileged Communications: Medical Report to Insurer; Cross-Examination of Witness.—An Oklahoma statute provides that the following persons shall be incompetent to testify:

A physician or surgeon concerning any communication made to him by his patient with reference to any physical or supposed physical disease, or any knowledge obtained by a personal examination of any such patient: *Provided, that if a person offer himself as a witness, that is to be deemed a consent to the examination.*

In an action by the plaintiff, the insured, to recover sick benefits under an insurance policy, which covered appendicitis but not salpingitis, "a disease peculiar to women," the Supreme Court of Oklahoma held that the lower court had not erred when it refused to permit the defendant insurance company to introduce in evidence, through the insured's attending physician whom it had called as a witness, a preliminary report of the plaintiff's illness, which report had been furnished to the insurer by the attending physician without the plaintiff's knowledge or consent. This medical report included a statement that in addition to acute appendicitis the patient had bilateral salpingitis, which information was obtained by the attending physician during the course of his professional attendance on the plaintiff. In the opinion of the court this statement in the report was privileged under the privileged communications statute, and the privilege was not waived by the submission of the report to the insurance company as proof of the plaintiff's illness. Furthermore, in the judgment of the court, this privilege was not waived by the plaintiff when at the trial she testified, on cross-examination by the defendant's counsel, concerning her health in general. When a plaintiff, continued the court, offers herself as a witness in an action to recover for sick benefits under an insurance policy but does not voluntarily testify specifically or generally as to the cause of her illness, or the condition of her health prior thereto, she neither by offering herself as a witness nor by any averment in her petition waives her privilege under the privileged communications statute against the disclosure by her physician of any knowledge with reference to any physical or supposed physical disease which he obtained by personal examination of her. As is provided in the statute, the privilege may be waived only in the event that the patient offers herself as a witness and testifies "on the same subject." Merely answering questions as to treatments received by her physician, in response to questions on cross-examination, was not voluntary testimony on the part of the plaintiff and did not waive the privilege guaranteed by the statute. Accordingly, the judgment in favor of the plaintiff was affirmed. —*Massachusetts Bonding & Ins. Co. v. Jones (Okla.)*, 94 P. (2d) 885.

Malpractice: Liability of Physician for Infection of Eyeball Following Surgical Removal of Cyst of Eyelid.—The plaintiff engaged the defendant, a physician but not a specialist in diseases of the eye, to remove a cyst from the "underside of her upper eyelid." He advised her that this could be done by a slight operation without causing pain or affecting her sight and that she would be cured in a short time. He everted the eyelid, made an incision and scraped out the cystic material with a curet. He then applied hydrogen peroxide and a 5 per cent solution of mild protein silver, placed a bandage over the eye and instructed the patient not to touch the bandage or her eye, to prevent infection. Thereafter he treated her daily for almost two weeks and then made arrangements for another physician to take over the case so that he might attend a physicians' meeting out of town. Up to the time he left he

repeatedly assured the plaintiff that her eye was "doing nicely" and was not infected. At the trial, however, he admitted that three or four days prior to his departure he had observed a white cloudy circular ring in the iris of the plaintiff's eye "around the outer portion, which gradually grew cloudy and continued cloudy." The day after the defendant left, the plaintiff called the physician who was to take the defendant's place during his absence. He found the "entire eyeball completely inflamed," refused to treat it and sent the plaintiff to an eye specialist. In spite of treatments for a few days the condition of the plaintiff's eye became worse and the eyeball had to be removed. The plaintiff later brought suit against the defendant physician for malpractice. From a judgment in favor of the plaintiff the physician appealed to the court of appeals of Tennessee, middle section.

The defendant contended that the judgment was not supported by the evidence and that the trial court had erred in not directing a verdict in his favor. He further contended that the infection of the plaintiff's eyeball was the result of syphilis which she had contracted in 1931 and which had become arrested following her discontinuance of treatment before a cure had been effected. However, a Wassermann test for syphilis, taken during the course of the treatment of her eye, was negative. There was no evidence, said the court of appeals, that the defendant injured the plaintiff's eyeball in operating on her eyelid, and there was no evidence as to the cause of the inflammation of the eyeball. So far as the record showed, the plaintiff's eyeball may have become infected by her own fault in adjusting the bandages or in rubbing her eye, or it may have resulted from an "abscess caused by syphilis." But, continued the court, the lower court would not have been warranted in directing a verdict for the defendant on the proposition that he had exercised due care and skill in treating the plaintiff's eye after the operation on her eyelid. The defendant admitted that before he had turned the case over to the second physician he had observed a white ring "around the outer portion" of the iris which gradually became cloudy and remained cloudy. Both the other two physicians who attended the plaintiff were of the opinion that her eyeball had been infected for several days prior to the time of the defendant's departure from town. In the judgment of the court, the defendant evidently did not know or was negligent in not observing the infection when he assured the plaintiff that her eye was "doing nicely." It was therefore a question for the jury's determination whether or not the defendant in treating the eye subsequent to the operation had possessed and exercised that reasonable learning, skill and experience ordinarily possessed and exercised by members of the medical profession in good standing under similar circumstances. The court could find no reason to disturb the jury's finding that he had not. Accordingly, the judgment in favor of the plaintiff was affirmed. —*Glover v. Burke (Tenn.)*, 133 S. W. (2d) 611.

- Western Surgical Association, Topeka, Kan., Dec. 6-7. Dr. Albert H. Montgomery, 122 South Michigan Blvd., Chicago, Secretary.

Current Medical Literature

AMERICAN

The Association library lends periodicals to members of the Association and to individual subscribers in continental United States and Canada for a period of three days. Three journals may be borrowed at a time. Periodicals are available from 1930 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 18 cents if three periodicals are requested). Periodicals published by the American Medical Association are not available for lending but can be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

- *Incidence of Syphilitic Aortitis in Representative Municipal Hospital. A. Gelperin, Cincinnati.—p. 340.
- Cardiovascular System in Pulmonary Tuberculosis. J. A. Sweeney, Philadelphia.—p. 345.

Incidence of Syphilitic Aortitis.—Gelperin studied the records of the 7,683 necropsies performed between 1926 and 1937 at the Cincinnati General Hospital. Microscopic evidence of syphilitic aortitis (excluding all developmental complications) was found in 700, or 9.1 per cent of the total. Variations in the incidence of syphilitic aortitis in necropsy groups depend on differences in the social status of the source population and on the number of Negroes who are included. Approximately 8 per cent of the white and 25 per cent of the Negro patients in a hospital caring for the indigent sick will have syphilis. By applying these percentages to the necropsy records studied by him the author finds that such a calculation shows that there should be 1,132 patients with syphilis (14.6 per cent). Since not all patients with syphilis have syphilitic aortitis, and estimations of its incidence vary from 50 to 90 per cent, an average figure of 70 per cent should give 792 cases of syphilitic aortitis, or 10.3 per cent. This predicted percentage is comparable to the actual incidence, which was 9.1 per cent. At least 1,200 patients with syphilitic aortitis are admitted to the Cincinnati General Hospital each year. The diagnosis of syphilitic aortitis therefore should merit more practical consideration than it has received. The problem might be solved by a better application of the knowledge of the pathologic changes of syphilis. Except during the relatively short early mucocutaneous infectious and late visceral stages, syphilis in its latent period is not moribund but smoldering and is slowly but surely destroying irreplaceable vital tissue. It is impossible to predict in whom it will develop and who will escape the disastrous developmental complications of syphilitic aortitis. Therefore it is suggested that "probable syphilitic aortitis" be added to each diagnosis of late latent syphilis in which previous treatment has been inadequate.

Immune Reactions of Pneumococcus Carriers and Non-carriers.—Finland and his associates carried out bacteriologic and immunologic studies on 126 interns, nurses, attendants, technicians and clinical clerks whose duties necessitated varying degrees of contact with pneumonia patients at the Boston City Hospital, where from 500 to 800 patients with pneumococcal pneumonia are treated each year. Bacteriologic studies were directed mainly to the isolation and identification of pneumococci from swabs from the tonsillar fossae and posterior pharyngeal wall. Pneumococci were identified on one or more occasions in seventy-one (56 per cent) of the 126 subjects. The percentage of carriers found appeared to be more or less proportional to the number of cultures made. Most of the patients who had pneumococci in their throat at the time of the first culture also had them in later cultures. These pneumococci were usually of the same type. Pharyngeal cultures were made of eighty-seven subjects either while they were having symptoms of acute respiratory infections or within a week after their subsidence. Pneumococci were found with about equal frequency in these cultures and in those when the subjects were free from respiratory infections. The distribution of types of pneumococci was similar in a general way to that found in most epidemiologic studies. Certain types of pneumococci, notably types I, VII, VIII, XIII, XVII and XXI, were more frequent than is usual among normal persons. Antibodies for homologous types were found frequently in carriers at the time when pneumococci were isolated. In a considerable number of the subjects the pneumococci were cultured before the corresponding antibodies were first demonstrated in the blood. In others, antibodies were present before the organisms were found in the pharynx. In many instances, antibodies persisted regardless of whether the carrier state continued or the organisms were no longer found. The association of antibodies in the serum with the finding of pneumococci in the pharynx was by no means constant in the transient or the chronic carriers. While it was difficult to trace direct exposures of carriers to patients infected with the same pneumococcus, there was indirect evidence of exposure to patients by some of the carriers of the less frequent types. More often the evidence pointed to exposure of the various carriers to one another rather than to patients. Pneumonia developed in four of the interns in the course of the study. These were not classic cases of lobar pneumonia and they do not shed much light on the relation of the immune mechanism to the inception of pneumococcal pneumonia. Two of the subjects were previously shown to be chronic pneumococcus carriers. The same type of pneumococci was found during the disease as was found previously and there was no significant change in the antibody status. The pneumonia of the other two interns was presumably transmitted from one to the other. In one a few type XVIII pneumococci were found during his illness; they were probably

incidental and their antigenicity could not be demonstrated. No pneumococci could be isolated from the cultures of the other intern during his infection, although he previously was a transient carrier of type XVII pneumococci. The predominant organism found during the acute illness of these two subjects was a slightly hemolytic streptococcus which was not fully identified. Their illness resembled that of atypical pneumonia, described recently as acute interstitial pneumonitis and sometimes loosely called "virus pneumonia" although a definite virus etiology has not been established. In none of the interns who had pneumonia did significant antibodies develop either to the pneumococcus which was found or to most of the common types associated with pneumonia. The observations lend further support to the antigenicity of type specific pneumococci in apparently healthy carriers, and those in the subjects in whom pneumonia developed indicate that pneumococci found in patients with atypical pneumonias may not be etiologically related to the infection.

Birds and Mosquitoes as Hosts for Encephalomyelitis Virus.—Davis investigated which mosquitoes native to Massachusetts were capable of transmitting eastern equine encephalomyelitis. Sixteen species of mosquitoes native to Massachusetts, including all the commoner members of the forty Culicinae known to the state, were obtained for study. In addition, *Aedes aegypti* was used as a control because it was already known to be a vector. The author also determined whether mosquitoes could become infected by feeding on wild birds, which may thus serve as a reservoir for the virus. He found that of the seventeen species of mosquitoes studied five (*Aedes vexans*, *Aedes sollicitans*, *Aedes cantator*, *Aedes atropalpus* and *Aedes triseriatus*) and a laboratory strain (*Aedes aegypti*) could transmit the virus of eastern equine encephalomyelitis from infected birds or mammals to other animals. No transmissions were obtained with the *Culex*, *Mansonia* and *Anopheles* genera of mosquitoes. Most mosquitoes of the genus *Aedes* probably can serve as vectors of the virus in the laboratory, but ecologic factors determine the importance of the different species in nature. If mosquitoes are the natural vectors of equine encephalomyelitis, *Aedes vexans* was probably the most important vector of the infection in the New England epidemic of 1938. Experimental evidence showed that birds (English sparrows, pigeons and cowbirds) could be infected with virus by the bite of infected mosquitoes and that such birds may serve as a source from which mosquitoes become infected. The results do not prove that birds are the natural reservoir of equine encephalomyelitis, but it is likely that mosquitoes which become infected with virus from such birds in turn infect horses, human beings, birds or other animals.

Surgical Treatment of Acute Cholecystitis.—From 1933 to 1938, 955 patients were admitted to the Los Angeles County Hospital with the diagnosis of biliary disease. Bonn and Bachhuber studied their records in an attempt to determine

whether the elapsed time from the onset of an acute cholecystitis to operation had any influence on complications and mortality. The criterion was the pathologic diagnosis rather than the surgeon's operative report. The policy of the hospital has been to defer surgical intervention until the acute attack has subsided, subject to the indications for emergency operations at the discretion of the attending surgeons. The patient has been ill usually from two to seven days before entering the hospital. In the entire group of 955 cases there were 704 surgical interventions. Acute cholecystitis was diagnosed in 251 instances. Six cases had to be excluded because of insufficient data, leaving 245. None of this group were operated on and fifteen died. Nine necropsies were done, and in all but two instances the cause of death was other than acute cholecystitis or its complications. All necropsies showed the presence of a cholecystitis. As 230 of the 245 patients who were not operated on apparently recovered and were dismissed from the hospital in from five to fourteen days, there is presumptive evidence that the incidence of perforation, gangrene and abscess may not be as high as some observers report. The patients operated on have been divided into three groups: 1. Operation was performed within forty-eight hours of onset on sixteen patients; eight cholecystectomies and eight cholecystostomies, with three deaths, a mortality of 19 per cent. 2. Sixty-four patients were operated on from forty-eight hours to the seventh day after onset. There were five deaths, a mortality of 8 per cent. Forty-eight cholecystectomies were done with four deaths, and sixteen cholecystostomies were done with one death. 3. There were 427 operations performed after the sixth day of onset. The greater portion of this group were operated on from the fourteenth to the twenty-first day after onset, the majority on the fourteenth day. There were twenty-three deaths, a mortality of 5.4 per cent. Twenty deaths occurred among the 390 cholecystectomies performed and three deaths followed the thirty-seven cholecystostomies. The authors conclude that operation within forty-eight hours of onset carried too high a mortality to warrant much consideration, especially in the wards of charitable hospitals, whose patients are frequently poor surgical risks and who often do not come to the hospital within forty-eight hours of the acute onset. Therefore any early operation, preferably cholecystectomy, should be done within six to twelve hours of onset. The peak of the disease is probably reached in from one to four days. In group 2 the mortality had dropped by 60 per cent, from the 19 per cent of group 1 to 7.8 per cent in group 2. In group 3 evidence of acute active pathologic changes in the gallbladder was found in 130 of the 427 patients in whom the condition had supposedly subsided. The majority of the 130 patients showed minimal clinical manifestations when operated on. Yet the mortality dropped from 19 per cent in group 1 and 7.8 per cent in group 2 to 5.4 per cent in group 3. Nine deaths in group 3 were due to accidental injuries of ducts and blood vessels; if these deaths were eliminated the mortality would be 3.5 per cent. The frequent occurrence of acute pathologic changes in groups 2 (twenty-nine instances) and 3 does much to influence the authors' belief that no absolute time can be set as to the opportune moment to operate. Therefore each case should be conducted on a knowledge of Touroff's pertinent facts and be sharply individualized. Except for those cases of perforation and gangrene which may apparently occur at any time, the mortality percentage will probably be lowest when operation is done about fourteen days after onset.

Meckel's Diverticulum.—According to Noel, twenty-five cases of Meckel's diverticulum were encountered in 12,000 intra-abdominal operations performed at the Henry Ford Hospital during the last thirteen years. Seventeen of these occurred between the ages of 20 and 50 years. The extremes of life were a baby aged 14 weeks and a man aged 77. There were fifteen male and ten female patients; all were of the white race. The diverticula vary markedly in size, shape, position and structure. The majority were approximately the size of a thumb. Their position in relation to the ileocecal valve varied from 2 inches to 3 feet from the cecum. The majority of the diverticula lay free except for their attachment to the ileum. Thirteen of the patients presented no symptoms referable to the diverticulum. These patients were operated on for other conditions

and the diverticulum was an incidental finding. In the other twelve patients the symptoms depended on the pathologic involvement of the diverticulum. Six were associated with symptoms of intestinal obstruction, two suggested appendicitis, one bled from the umbilicus and three from the intestine. The preoperative impression was correct in only three cases. Treatment is always surgical intervention. The pathologic process resulting as a complication of the diverticulum must be given first attention, but the diverticulum should usually be removed. The diverticula reported were seen by seven different surgeons and treatment was of five different types. The technic for excision of the diverticulum is usually that used for the appendix. Resection of the intestine and inversion should be carried out only for special indications. Meckel's diverticulum should be looked for if the lesion found at operation is insufficient to account for the preoperative symptoms and signs. Two patients died: the 77 year old patient three days after operation and a woman of 56 from intestinal obstruction associated with a strangulated hernia. Only twenty of the twenty-five patients had any form of treatment directed to the diverticulum, giving a mortality rate of 10 per cent. The prognosis is good for complete recovery after the diverticulum is removed. Although the follow-up has been inadequate, none of the patients have returned for treatment for any cause associated with the diverticulum.

Tetanus.—Kirtley presents data on fifty-two cases of tetanus in the Vanderbilt University Hospital and eight cases in St. Thomas Hospital observed during the last fourteen years. There were thirty-two patients whose symptoms appeared within ten days after the initial injury (early tetanus) and twenty-eight whose symptoms occurred after more than ten days (late tetanus). The mortality among the early cases was 71.8 per cent and among the late cases 17.8 per cent. Puncture wounds of the extremities by nails, splinters, thorns and rake prongs were the commonest agents of injury. Lacerated wounds were the next most frequent. The mortality rate shows little change from year to year. During the first seven years of the study it was 45.8 per cent among twenty-four cases and in the last seven years 47.2 per cent among thirty-six cases. Three of the sixty patients received prophylactic injections of at least 1,500 units of antitoxin within twenty-four hours of the initial injury. Two of these patients died and one recovered. It is generally assumed that prophylactic antitoxin will prevent tetanus, but from 5 to 10 per cent of the patients with tetanus have had prophylactic antitoxin. The strongest evidence for prophylaxis is the 0.117 per cent of tetanus among more than two million wounded British soldiers who had received antitoxin. The debriding and irrigating of many of these war wounds may have also been a big factor in lowering its incidence. The incidence of tetanus has steadily decreased with each war as medical care and prophylaxis have improved. Comparable figures for tetanus in civil life are not available. The importance of incising the site of infection and removing all foreign material has been urged by many investigators. In the author's series some surgical procedure was instituted in seven cases with one death. Twenty-seven of the fifty-three patients whose wounds did not receive any surgical treatment died. The importance of wound care is again emphasized in the one patient who would have been expected to die but who recovered. This boy of 10 years cut his leg on a piece of glass and the wound was sutured at once. Three days later trismus and convulsions developed. The wound was reopened and irrigated, and wet dressings were applied. The child had a high temperature, tachycardia and all the unfavorable prognostic signs but recovered. The fact that failure to drain a localized infection containing tetanus bacilli may result in a fatality in spite of long incubation and survival periods and more than 200,000 units of antitoxin is shown by the following: A boy of 17 years injured his hand with a blank cartridge and a week later mild tetanus developed and he entered the hospital. Despite large daily doses of antitoxin he became progressively worse and died sixteen days after admission. Necropsy showed a palmar abscess containing powder granules, pus and tetanus spores. Twenty of the twenty-eight patients who died had wounds so located that incision or excision could have been done. Half of them died within twenty-four hours

after admission, making it questionable whether any measure would have been of benefit. The other ten patients lived from two to sixteen days. It would seem desirable to incise the infected wound and convert it into an open wound in which anaerobiosis would be discouraged if not prevented. If further toxin formation can be prevented after hospitalization and the free, unfixed toxin neutralized, some of the patients who live four or five days may be saved. Antitoxin is best administered by the intravenous and intramuscular routes. The amount given seems to make little difference in mortality. Deaths were slightly less in the group receiving from 25,000 to 50,000 units in the first forty-eight hours. More than 43 per cent of the patients who died received more than 50,000 units within a few hours after admission. Avertin with amylene hydrate was given only those patients who had clonic convulsions; half recovered and half died. Phenol intravenously was given to seven patients, with two deaths. The two who died had short incubation periods, while those recovering had incubation periods of more than ten days. One patient with an incubation period of sixteen days received phenol alone and recovered.

Prognosis in Syphilitic Aortic Insufficiency.—Kampmeier and Combs studied the records of 163 patients with syphilitic aortic insufficiency in order to determine the part anti-syphilitic treatment played in prolonging life. They also analyzed the relationship of congestive heart failure, free aortic regurgitation, sex and manual labor to longevity. Serologic tests for syphilis were positive in 139 cases and negative in twenty-three. Nineteen showed collateral evidence of syphilis and four presented no such evidence. Fifty-four and six tenths per cent died within the first three years after onset of symptoms and 19 per cent after three years; 11 per cent lived less than three years and 15.4 per cent survived this period. Practically all the patients were in the fifth decade of life. Of the group who died twelve, or 10 per cent, lived an average of 89.2 months and seventeen, or 39.5 per cent, of the living group survived an average of 112.8 months. The latter group had experienced symptoms for only about eleven months before coming under observation, whereas the former had symptoms for twice as long. The distribution of the dead and the living patients with relationship to race, sex and duration of life indicates that manual labor accelerates the progress of syphilitic aortic disease; 39 per cent of the patients who died within three years of the onset of symptoms were laborers and only 22 per cent of those who survived longer than three years were laborers. Two thirds of the ninety-one Negro men died within three years, fifteen died within a period of from thirty-seven to 138 months and only nine were alive from thirty-seven to 168 months after the onset of symptoms. Less than one half of the white men and Negro women died within three years, and about one fifth were alive from thirty-seven to 168 months after the onset of symptoms. There were only eight white women, but only two of these died within three years and one half were still alive from thirty-seven to 168 months after the onset of symptoms. Of those who died within three years 80 per cent were men, whereas after this

period men accounted for 67.7 per cent of the deaths. The aortic lesion was a chance finding among only twenty-five of the patients. Only fourteen of the 163 patients had had adequate treatment (at least eight injections of an arsenical plus twelve or more injections of heavy metal compounds or twenty-four or more injections of heavy metal compounds) in the past. Following the diagnosis of syphilitic aortic insufficiency only four of eighty-nine patients dying within three years and four of thirty-one dying in from thirty-seven to 138 months had received adequate treatment. Two of the latter group were women and lived seven and eleven years respectively. Likewise twelve of eighteen patients alive up to thirty-six months and twelve of twenty-five alive from thirty-seven to 168 months had received adequate treatment. Of the forty-three living patients eighteen were women, and one half of the twenty-four adequately treated patients were women. The data for the patients who died after twelve months from the onset of symptoms (others are not included) show that those who received inadequate treatment lived for 36.2 months as compared with 60.3 months for the adequately treated group. The duration of life of adequately treated Negro men was about equal to that of inadequately treated Negro women. Inadequately treated white men lived an average of 40 per cent longer than inadequately treated Negro men. Of twenty-two patients alive more than twelve months after the onset of symptoms, twenty-two have had adequate treatment and have lived on an average of 60.3 months. The seventeen who were inadequately treated have lived a total average of 80.6 months. Therefore the study does not indicate that adequate antisyphilitic treatment has a favorable influence on the prognosis of syphilitic aortic insufficiency. Of the 120 patients who died, twenty-nine died of other than a cause related to the heart.

Convalescent Scarlet Fever Serum.—Viole used human convalescent scarlet fever serum for thirty-seven patients with streptococcal infection of the ear, nose or throat. Some of these were complications of scarlet fever or scarlatina. Of sixteen persons having otitis media and mastoiditis, nine required mastoidectomies. In four cases in which the serum was administered there was an immediate drop in temperature and lessening of the toxic symptoms with rapid, uneventful recovery. In seven the convalescence was slower but far better than might have been expected had the serum not been administered. The results were debatable in only four, as no demonstrable changes could be attributed to the serum. Only one of these sixteen patients died in spite of an injection of scarlet fever serum, which seemed to have no effect. Necropsy revealed that death was due to an acute streptococcal septicemia. Eight of the thirty-seven patients received sulfanilamide in addition to the serum. It made little

if any difference in the course of the disease and the patient's recovery. However, in the presence of a grave illness neither should be denied if indicated. There were five cases of streptococcal meningitis secondary to mastoiditis in which surgical intervention was performed. Two of these patients improved immediately after receiving the serum, although one had been receiving sulfanilamide without much effect. Convalescence was uneventful and the results were excellent. A third patient showed some immediate improvement but a large abscess developed in the left buttock at the site of the intramuscular injection of the serum. Her progress was retarded until the abscess was opened and drained. The two remaining patients of this group received sulfanilamide in addition to serum. One made an uneventful recovery. The other improved slowly, but four days after she had been discharged from the hospital a diagnosis of scarlet fever was made. The value of the serum may be considered questionable. Another patient immediately after mastoidectomy on the left side with ligation of the jugular vein received 40 cc. of scarlet fever serum and his temperature dropped to normal, where it remained for four days, when it rose suddenly to 105 F. The mastoid wound was reopened but no pathologic change was found. Two subsequent injections of serum, 20 and 40 cc. respectively, failed to elicit any response and the patient died. There were four cases of laryngotracheobronchitis and three of streptococcal pharyngitis. Three tracheotomies were performed. The rate of recovery and definite signs of improvement were much slower in three patients who were given sulfanilamide in addition to the serum. The others who received only serum, except one on whom a tracheotomy had been performed, improved immediately. The author states that the most dramatic improvement following serum occurred among five cases of streptococcal sore throat, definitely placing streptococcal sore throat among the curable diseases. In the series there was a retropharyngeal abscess with complicating cervical adenitis, toxic anemia, Ludwig's angina and otitis media. In spite of injections of serum this patient's progress was slow until the abscess was opened and drained, when the convalescence was rapid and uneventful. This emphasizes the benefits of early treatment. One instance of beginning peritonsillar abscess responded well to scarlet fever serum and the patient improved without surgical intervention. On the other hand its value in a case of cervical adenitis was questionable. The patient also received sulfanilamide and, though her convalescence was uneventful, it was decidedly slow. There was only one reaction to the serum. This patient had a long history of allergy to various things and entered the hospital with asthma, cervical adenitis and pneumonia complicating scarlet fever. Urticaria developed after 40 cc. of the scarlet fever serum, and no more, was given. After adequate doses of sulfanilamide she recovered. Human convalescent scarlet fever serum produces no foreign protein reactions and sensitizations as does animal serum, and such reactions as may occur are easily controlled.

Frontal Bone Osteomyelitis.—Jones reports thirteen cases of osteomyelitis of the frontal bone and emphasizes the necessity for early diagnosis. He stresses the fact that swelling, edema and pain over the frontal sinus are of more value than a roentgenogram, as the infection is existent from seven to ten days before there can be x-ray evidence of it. Two of the author's cases followed injury and were not connected with sinus infection, four presented intracranial involvement and seven did not. He does not think that any definite operative procedure can be followed in these cases. It is not necessary to block off and remove a whole area of the frontal bone because the diploic spaces are tortuous. The operative procedure which he uses follows along the diploic spaces. The incision should be sufficiently large to uncover a large amount of bone for inspection, and bone removal should extend laterally far enough to reach the outer limit of the frontal sinuses. He has secured good results by more conservative incisions than that from eyebrow to eyebrow and splitting up the middle of the forehead. He has used the hairline incision as brought out by Furstenberg with almost no visible scarring, being careful to preserve the periosteum. With plenty of assistance in elevating the scalp, an excellent view can be obtained of the questionable area. This incision also leaves little scarring. The end results in his cases

indicate that the enormous disfigurement caused by keeping the flaps separated during the healing is not necessary. He concludes from a rather incomplete survey of the literature and his observations that generalized osteomyelitis is often inexcusably overlooked.

Vitamin A Intake and Biophotometer Readings.—Isaacs and her associates examined 143 healthy medical students in an endeavor to correlate their vitamin A intake with their biophotometer readings. Twenty of the subjects had ten consecutive daily readings in order to determine their day to day variations and the variations between different persons. The authors present the results of their attempts to produce a disturbance of vitamin A absorption and dark adaptation by giving large doses of liquid petrolatum to twenty-eight students (using twenty-nine others as controls), a disturbance of dark adaptation by a vitamin A deficient diet in three students and the response of patients to vitamin A. The biophotometer readings of the twenty students chosen for intensive study and of the other 123 tested showed frequent wide daily variations and also that a subject might appear deficient one day and normal on all ensuing days. In the experiment in which 5 cc. of liquid petrolatum per kilogram of body weight for as long as 131 days was used to impair vitamin A absorption the biophotometer did not detect any correlation between the dietary vitamin A of these or of normal subjects, their biophotometer performance and possibly presumptive clinical signs of hypovitaminosis A. Supplements of oil concentrates providing for several months 200,000 units of vitamin A and 2,700 units of vitamin D daily produced no apparent change in any of the subjects. The three subjects who lived on a diet containing not more than 74 U. S. P. units of vitamin A for forty-three, forty-nine and forty-nine days, respectively, failed to show more than a suggestion that their stores of vitamin A were being depleted as determined by dark adaptation levels. Subjective symptoms suggestive of a possible temporary hypovitaminosis were reported on the fourteenth and sixteenth day respectively by two of the subjects. The results are interpreted to indicate failure to produce definite evidence of deficiency after forty-nine days of a diet containing 74 units of vitamin A. The authors believe that their subjects must either have had large stores of vitamin A, were unsusceptible or that it takes a long time to manifest definite evidence of deficiency. In view of their results and the fact that several observers have reported a probable general vitamin A deficiency amounting in some areas to as high as 52 per cent, it occurs to them that (1) the average American diet may be deficient

in available vitamin A or its precursors, (2) the standard of vitamin A intake on which subjects are judged to be deficient is questionable and (3) the procedures being used for measurement are recording something other than vitamin A deficiency. They incline toward a combination of the latter two possibilities. It is their opinion that subjective factors involved in the determinations of all types of visual tests should be recognized and an attempt be made to control them when measurements of dark adaptation levels are made; also that significance should not be attached to minor fluctuations in dark adaptation in terms of vitamin A deficiency unless statistical methods are used to test the reliability and validity of the differences.

Retinal Veins in Diabetes.—Ophthalmoscopic examinations of several hundred diabetic patients, according to O'Brien and Allen, have revealed many with typical retinitis. Almost invariably sclerosis of the retinal vessels was in evidence and occasionally varices of the retinal veins were observed. These venous changes occurred almost exclusively in patients with diabetes and arteriosclerosis, but occasionally they were present in those with arteriosclerosis alone. Most frequently the varices were found in those with poorly controlled, long-standing diabetes. From the literature, in which eight cases are reported, it appears that varicosities of the retinal veins are rare and apparently occur almost exclusively in adults with poorly controlled diabetes and arteriosclerosis. The authors cite twenty-one patients from 36 to 65 years of age having diabetes with retinitis and retinal varices, who showed symptoms of diabetes for from two to twenty-five years, with an average of ten years. The diabetes was poorly controlled in every instance. The systolic blood pressure ranged from 108 to 240 mm. of mercury and the diastolic pressure from 65 to 110 mm. On physical examination nineteen of the twenty-one patients were found to have generalized arteriosclerosis and five showed nephrosclerosis. Nine patients had enlargement of the heart and five had coronary disease. Other complicating conditions (gangrene, ulcers, edema) were encountered. The vision of sixteen patients was diminished. In every case the retinal vessels were sclerosed and hemorrhages were seen in the retina. In all but one, small sharply margined, yellowish white areas of retinal degeneration were present. Woolly areas of cytoid degeneration were observed in fifteen patients, proliferating retinitis was seen in one or both eyes of nine patients and hemorrhages in the vitreous were present at some time in three. All these patients showed varicosities, most frequently in the larger retinal veins. They did not appear to have any relation to arteriovenous crossings. In some eyes the varices alone gave evidence of venous changes, but in others a white line along either side of the vessel gave proof of sclerosis. Frequently the affected vein showed constrictions of the lumen alternating with varices, thus giving a beaded or sausage-like appearance. In five cases venous thrombosis was present in either the central vein or one of its branches. Under the microscope the veins of an eye with secondary glaucoma removed from one of these patients appeared sclerosed, the wall showing variations in thickness, hyaline degeneration, endothelial proliferation and thromboses. Varices in the retinal vessels were observed in considerably less than 1 per cent of patients with diabetic retinitis. Retinitis of diabetes is not perhaps the best term for the condition and retinosis is suggested.

Absorption and Excretion of Sulfapyridine.—Kinsman and his co-workers have given sulfapyridine to 131 patients. The concentration of the drug in the blood, its absorption and its elimination have been studied in forty-six cases (thirty-eight of pneumonia, one of empyema, one of gonococcal arthritis, one of typhoid and five of Streptococcus viridans endocarditis). The drug was administered orally. Absorption was erratic, the height of the absorption curve was unpredictable from identical doses and from patient to patient, and there was no correlation between the size of the dose and the height of the blood concentration curve. Generally the blood concentration was higher following a dose of 2 than of 4 Gm. About 60 per cent of the patients vomited. Vomiting was more frequent after an initial dose of 4 than of 2 Gm. Therefore the routine employment of an initial dose of 2 Gm. is recommended. The cause of the vomiting was not clarified but the authors feel that it is of central and not of gastric origin. It is not due to an increased concentration of the acetylated form of the drug, for among the patients who vomited this form of the drug was much lower than in the ones who did not vomit. Acetylation or conjugation of the drug occurred rapidly; about 35 per cent of it being acetylated within the first hour. Throughout the course of administration about 33 per cent of acetylation is present, although it varies from 0 to 100 per cent. During elimination acetylation is much greater than at any other time. No evidence was found that the degree of acetylation bears any relation to the total concentration of the drug in the blood. After the drug is withdrawn it is at first eliminated rapidly, then more slowly, so that as long as five days later appreciable quantities can still be found in the blood and urine. The free form is eliminated more rapidly than the acetylated form. The drug disappears from the urine at about the same time as from the blood. Quantitative determinations show that from 21 to 56 per cent of the drug can be recovered from the urine, the average being 30 per cent. The authors conclude that, in order to ensure the maximal recovery rate, frequent blood concentration studies should be made of every patient with pneumonia (103 of their whole series had pneumonia, six of them died) and if the patient does not seem to be doing well and the blood concentration is below 6 mg. per hundred cubic centimeters the drug or its sodium salt should be administered parenterally. Only 40 per cent of the patients with bacteremia recovered with a blood concentration less than 6 mg. per hundred cubic centimeters, whereas under the same conditions 70 per cent of patients with a negative blood culture recovered.

Aminophylline for Bronchial Asthma.—From July 1938 to May 1939, according to Carr, forty-one patients with acute bronchial asthma were treated at Bellevue Hospital. Twenty-two of these were refractory to epinephrine and their acute

attacks were treated by intravenous injections of aminophylline. The aminophylline was given undiluted, 0.48 Gm. in 2 cc. of aqueous solution. The entire amount was administered intravenously within two minutes. About a third of the patients showed one or more of the following symptoms: dizziness, nausea, retching, vomiting, "pounding of the head," "burning in chest and head" or head and chest pain. No alarming effects were observed, and neither did striking or permanent effects of pulse or blood pressure ensue. The duration of disease varied from one to twenty years. Half of the patients obtained immediate relief. The effect in others was evident in from five to thirty minutes. The duration of benefit was from one hour to the absence of a recurrence over a period of days. It was never necessary to give more than one injection within a period of less than two hours. The effectiveness of epinephrine may have been restored in view of the fact that half of the patients required only one injection, were subsequently discharged and apparently did not have another refractory attack. Eight of the twelve patients who received intravenous injections of aqueous solution of aminophylline for acute asthma without a history of its previous use obtained immediate and striking relief, and four obtained relief within ten minutes. Minor toxic symptoms occurred among one third of the patients. All stated that they experienced greater relief than that given by epinephrine during previous acute attacks. Eight patients who had been given epinephrine by the ambulance surgeon or admitting physician were all benefited when aminophylline was given from twenty-five minutes to twenty-four hours later. Three had immediate relief and the others obtained relief in from twenty to fifty minutes. Three had minor toxic symptoms. Two patients had asthma of an allergic type, and these two responded less favorably.

Embryoma of Testis.—Melicow reports an embryoma of the testis the microscopic picture of which he interprets on the basis of pathologic embryology. The patient, 28 years of age, presented a hard, painless, nontransilluminating mass in the right side of the scrotum. The condition had been present for four months. The Aschheim-Zondek test was strongly positive. A right orchidectomy was performed. The immediate recovery was uneventful, but the Aschheim-Zondek test

remained strongly positive. Bilateral gynecomastia and pulmonary metastases developed and caused hemoptysis. The patient died three months after the operation. The gross specimen presented areas of hemorrhage and necrosis within a relatively solid grayish pink tumor. Scattered among dense collections of variegated cells were a number of simple ring-like structures composed of ovoid cells characterized by an inner cell mass. The latter resembled the blastula stage of mammalian embryos. A count of the embryo-like buds in any one slide, when compared with the size of the specimen, indicates that the tumor probably contained millions of such structures. The blastula stage was seen often. In a few embryonic buds there was a suggestion of the formation of the notochord and splitting of the mesoderm to form the celomic cavity. Masses of syncytial cells resembling the chorionic epithelium seen in pregnancy were irregularly distributed throughout the specimen. This observation, plus the intense chorionic gonadotropic reaction and the gynecomastia, the author believes, support the conclusion that the tumor dealt with is one containing numerous embryos of varying stages of development. The blastulas were the youngest ever seen in the human being.

Malignant Testis Tumors and Gynecomastia.—Gilbert cites six cases of malignant testis tumors associated with gynecomastia and data on 129 cases from the literature. The study includes clinical examination for sperm in two cases, and differential qualitative determination of gonadotropic hormone output on hypophysectomized rats. The four other unpublished reports are personal communications. He divides the total of 135 cases of gynecomastia into two groups. Group 1 includes 103 cases associated with teratoid tumors. There were fifty-four primary testicular tumors, seven so-called extragenital chorionepitheliomas, eleven apparently misdiagnosed chorionepitheliomas and thirty-one teratoid tumors with a clinical course strongly suggesting the presence of chorionepitheliomatous elements. Group 2 comprises twenty cases which were eliminated from discussion in the group of true choriogenic tumors with gynecomastia. The mammary stimulation was nonfunctional and not related to the testis tumor. The characteristics of the syndrome of choriogenic gynecomastia with testis tumors consist of (1) chorionepithelioma in the primary or metastatic tumor, (2) gynecomastia, usually bilateral, with glandular tissue hyperplasia, often the only symptom present, (3) enlargement and/or hyperpigmentation of the areolae, (4) physiologic activity manifested by either gross or microscopic secretion in the breasts, (5) high titers of choriogonadotropic hormones and the presence of estrogen, (6) histologic changes in the pituitary gland described generally as "pregnancy cells" and (7) hyperplasia of the prostate and/or seminal vesicles.

Sulfathiazole Treatment of Gonorrhea.—Culp used sulfathiazole in the treatment of thirty-eight male patients with gonococcal urethritis. Twenty-one of these have been followed regularly since the drug was discontinued and seventeen of them have had no recurrence to date and appear to be cured. There were two frank failures and one recurrence. Anemia developed in one patient and he was unable to tolerate sulfathiazole. Six of the seventeen apparent cures were of patients with both anterior and posterior urethritis, some of which had further complicating manifestations of gonorrhea. Two of the cured patients had failed to improve on sulfanilamide. Most of the patients received 1 Gm. of sulfathiazole every six hours for an average of 9.3 days. The discharge disappeared on an average of 2.7 days in those patients in whom it was limited to the anterior urethra and on an average of 5.2 days when complications were present. Eight of the thirty-eight patients appeared to be well but failed to return after sulfathiazole was discontinued. The dosage and duration of their treatment was about the same as in the well followed cases. Urethral discharges disappeared on an average of 2.8 days, and all the patients were free from gonococci when last seen. The remaining nine patients have had disappearance of their discharge and their urethral cultures are negative, but they are still taking the drug. Six of these had posterior involvement and three involvement limited to the anterior urethra. In the latter group the discharge disappeared in two days and in the com-

plicated cases the duration of exudate averaged 4.7 days. Only two instances of toxicity (one of anemia and one of leukopenia) were encountered, although the blood and urine of every patient were analyzed frequently. The best results were obtained with those patients who received 1 Gm. of sulfathiazole every six hours until the voided urine was free from shreds. To avoid urolithiasis and leukopenia the fluid intake was intentionally not reduced. The blood level of sulfathiazole only once reached 4 mg. per hundred cubic centimeters. Generally it was between 2.5 and 3.5. A higher blood concentration of the drug does not appear necessary and limitation of fluids should be avoided. Sulfathiazole apparently is of great value in the treatment of acute gonorrhea (posterior and anterior) and it compares favorably with other sulfonamide derivatives.

Treatment of Neurosyphilis.—The efficacy of chemotherapy, particularly sobisminol mass developed by Hanzlik, following hyperpyrexia for the treatment of neurosyphilis is discussed by Carlisle and Bowen, by McClintock and by Johnson. Carlisle and Bowen point out that hyperpyrexia induced by malaria or short wave diathermy should be complemented by chemotherapy, as it is unlikely that pyrexial therapy ranging from 104 to 107.6 F. will uniformly and for long enough heat all the tissues of the body to this spirocheticidal point. Therefore they believe that chemotherapy should take care of any spirochetes which escaped the spirocheticidal effects of the heat. For this McClintock believes that sobisminol mass orally is indicated, as the daily urinary bismuth excretion level at from 3 to 5 mg. necessary for effective spirochetal destruction is easily maintained by its continued administration. This has been shown by various investigators. This level of excretion was easily maintained for the four patients treated at the Veterans' Administration Facility* at Palo Alto, Calif., by the daily oral administration of 900 mg. of sobisminol mass for as long as eight weeks. Mild toxic symptoms, nausea, vomiting, grip, stomatitis, anorexia and a bismuth line do occur but did not in their patients. However, the toxicity is immediately relieved when the drug is discontinued. Because of toxic symptoms treatment with sobisminol mass had to be discontinued permanently with four and temporarily with seven of ninety patients treated by Scholtz, McEachern and Wood. Johnson discusses the incidence of optic nerve damage, and toxic amblyopia as by-effects of trypanamide treatment of neurosyphilitic patients. He recommends routine ophthalmologic examination of the neurosyphilitic patient on admission to the hospital, as these will make subsequent comparisons possible. It has been stated by Moore that if any visual impairment is to occur it will appear by or before the fifth weekly injection of trypanamide. If no impairment is apparent by the twelfth injection the drug may thereafter be administered with impunity. All patients should be cautioned to report any visual disturbance following trypanamide therapy. Regardless of how psychotic the patient may be, any report of a visual change should be heeded and acted on immediately. At this time probably no changes will be apparent in the disk head provided treatment (hyperpyrexia and chemotherapy) for the neurosyphilis was instituted fairly early. Field changes must now be relied on and if present and trypanamide is discontinued it is usually possible to arrest the optic process.

Tuberculin Test.—Soderstrom points out that the belief that allergy and immunity to tuberculosis are one and the same thing is refuted by the analysis of the statistically significant studies on the tuberculin test made during the last few years in Tennessee. Too many indisputable x-ray evidences of healed tuberculosis were found in negative reactors to allow the standard teachings to go unchallenged. The Tennessee studies revealed that a person giving a negative tuberculin reaction is not necessarily one who has never been infected by the tubercle bacillus. The phenomenon of "allergy reversion" has been shown experimentally and can be deduced from available figures based on clinical observations. If, as is acknowledged, a relatively few years ago human beings were approximately 100 per cent positive reactors from the teen age to senility, what is there to explain the fact that those young adults, who were all positive a couple of decades ago, are approximately 50 per cent negative reactors today? It seems to the author that they have lost their allergy to tuberculin or that it has become diminished to the point that it is not detected by the cutaneous test. They have reverted from positive to negative states and there is no evidence that they have lost their expected resistance as acquired from a primary infection. Long explains this as a reversion due to lack of repeated allergy-producing doses of tubercle bacilli, which seem to be necessary for the maintenance of allergy. To argue that the rapid decline in positive reactors is making for a race of increased susceptibility is not considering inherited racial immunity, which, having been created during the centuries past, is hardly dependent on created allergy in the individual. At present it seems that the value of the tuberculin test, though changing, has led into newer and probably more fruitful fields of application. The clinical case of tuberculosis, the sick patient, will almost invariably react to a properly applied tuberculin test. A true tuberculin negative reactor rarely could have tuberculosis. This statement is of increasing importance when one considers that the day of almost universal positive reactors among adult population groups is passing into one in which the positive adult reactor is in the minority. The meaning of a positive adult reactor with or without pulmonary symptoms is becoming more and more indicative of pathologic changes. There may be

the day when this is just as true as the relation that a positive Wassermann reaction bears to the person with clinical syphilis. In the light of the changing values of the tuberculin test its use in mass surveys and case finding attempts must be reappraised. The author does not believe that the justification for mass group testing exists today that existed several years ago. He does not question the merits of testing the school child, with the aim of using this to impress him with tuberculosis education. However, he points out that its most fruitful application as a case finding procedure is in the physician's office in his routine practice. If the clinician will remember that tuberculin should be used on the individual patient in question, not on the patient's relatives, and that all negative reactors should be rechecked with a stronger solution of potent tuberculin, using the proper intradermal technic, he will find an inexpensive procedure offering a substantial reward for the effort expended. Soderstrom believes that official health agencies can best give their attention to proper follow-up of known cases and of tuberculosis contacts through the practicing physicians' cooperation who use tuberculin in their practice. This cooperation will speed the day when eradication of tuberculosis may be a reality rather than a mere probability.

Treatment of Mixed Tumors of Parotid Gland.—Patey reviews the present position on the treatment of mixed tumors of the parotid gland. He bases his conclusions on the experience of others as revealed in recent literature and on the surgical and x-ray records of cases seen at the Middlesex Hospital, some of which were under his care and some under the care of his colleagues. He concludes that the natural course of mixed parotid tumors is to increase in size at varying rates, leading to a corresponding degree of deformity but otherwise causing little disability. Spontaneous malignant change in a mixed tumor is so rare that it may be ignored. Surgical enucleation alone may be satisfactory, but recurrence is seen in too many cases, and in some of these the recurrence is directly responsible for the death of the patient. There should be no hurry to treat these tumors. A period of observation to determine the rate of growth may be advantageous. In mixed parotid tumors appearing late in life, and in slowly growing tumors appearing earlier, the correct treatment may be to do nothing. Radical excision of the parotid is too deforming to be a routine treatment. However, in exceptional cases this may be the correct procedure in which complete facial palsy is justifiable. Irradiation alone is not a satisfactory form of treatment. It may be a useful diagnostic measure, indicating whether the tumor is or is not radiosensitive. Preoperative irradiation is valuable, since it renders the capsule of the tumor tougher and less liable to rupture during operation. Enucleation followed by irradiation appears to be the best active treatment for mixed parotid tumors.

Toxicity of Certain Arsenicals Used for Neurosyphilis.—From 1936 to July 1939 Ross treated 256 cases of neurosyphilis with tryparsamide and 314 with sodium succinylmethylamide-*p*-arsonate (neocryl). The standard dose of each drug was 3 Gm. intravenously once a week until 30 Gm. had been administered. A survey of the records of the cases at least twelve months after the end of treatment has confirmed the early impression that the results obtained with neocryl are in no way inferior to those of tryparsamide. As the work progressed and it became evident that neocryl was relatively harmless, it was chosen for all cases exhibiting visual disturbance, optic atrophy, in which tryparsamide is contraindicated. The usual toxic reactions were considerably more frequent in the tryparsamide series than in the neocryl group. Neocryl did not cause any functional visual disturbance, but in one patient with tabes dorsalis after nine doses sudden and complete blindness occurred. The blindness which followed in three cases treated by tryparsamide was gradual in its development. In three cases optic atrophy present

before the administration of neocryl became worse but in nine other known cases no ill effect was produced. Of 256 cases treated with tryparsamide seventy-eight exhibited toxic manifestations, whereas of 314 cases treated with neocryl only twenty-seven had toxic reactions. Both compounds may cause jaundice, dermatitis and other undesirable reactions seen after the administration of trivalent arsenicals; but it is chiefly in its relative innocuity to the optic nerve that the advantages of neocryl become apparent. Visual disturbance occurred in forty-seven of the seventy-eight cases which reacted unfavorably to tryparsamide: in thirty-six the signs were subjective but in eleven they were objective; in three total blindness developed. Neocryl was accountable for only one case of visual damage. The author believes that neocryl is to be preferred in all cases of neurosyphilis in which the administration of pentavalent arsenicals is necessary.

*Treatment of Tetanus with Evipal Soluble and Sulfapyridine. J. Bryant and H. D. Fairman.—p. 263.

Evipal Soluble and Sulfapyridine for Tetanus.—In the course of an outbreak of cerebrospinal meningitis in the Dinka districts in Equatoria province of the Anglo-Egyptian Sudan, Bryant and Fairman observed that patients with tetanus were occasionally brought to Sudan Medical Service dressers in treatment centers established in the infected districts. Some dressers had seen tetanus before and recognized it; others had not. Relations of the sick, if told that the patient had not cerebrospinal meningitis but tetanus, as a rule demanded treatment and lumbar puncture. The treatment was always given by the dresser as for cerebrospinal meningitis by lumbar puncture and injections of sulfapyridine. During the constant patrolling of the epidemic areas the authors saw these cases in treatment centers and administered evipal soluble (evipal sodium), leaving enough of the drug with the dresser to keep the patient quiet or, if necessary, anesthetized for three or four days. All of the twenty-two cases of tetanus recorded here were typical and severe and without treatment most would probably have had a fatal outcome in a day or two. However, under treatment with sulfapyridine and continued or intermittent narcosis with evipal soluble all but five recovered. The authors also state that during the last few years cases of tetanus were occasionally treated with evipal soluble alone. Results have been fair and unexpected recoveries made. Numbers are too small for analysis, but if the patient could be kept alive for five or six days he seemed to have a good chance of recovery. Lumbar puncture was always performed. Recovery in these cases was always extremely slow and wasting was pronounced. In the light of this experience with evipal soluble alone, the authors think that in the cases treated with sulfapyridine and evipal soluble, recovery has been too rapid and mortality too low to be explained away entirely by the muscular rest produced by prolonged narcosis. They suggest that it is possible to save many patients with tetanus in remote places where high temperatures and inaccessibility preclude the use of serum.

*Parinaud's Conjunctivitis. A. Castelli and L. Molina.—p. 179.

Parinaud's Conjunctivitis.—Castelli and Molina were able to isolate from an exogenously infected human subject an acid-fast organism which they regard as the true infective agent in Parinaud's conjunctivitis and as a new species of mycobacterium. This organism is intensely pathogenic for certain laboratory animals but induces a mild infection in man. The authors were able to observe its morphologic, biologic and staining characteristics under aerobic and anaerobic conditions during the course of three years and conducted extensive experiments on more than 200 animals. The bacillus, in their opinion, is definitely differentiable from *Mycobacterium tuberculosis*, human and bovine, by significant biologic and cultural traits. Anatomopathologic and microscopic examinations of the lesions produced in the lungs, liver, lymph nodes, iris and conjunctiva and tuberculin assays for differential diagnosis confirmed their discovery. Animals immunized against tuberculosis by repeated inoculations with BCG vaccine succumbed to the infection of the new organism but successfully resisted high doses of virulent Koch bacillus. The authors believe that Parinaud's conjunctivitis is a definite disease entity and not a syndrome provokable by a variety of pathologic causes. Atypical cases of Parinaud's conjunctivitis are probably of tuberculous origin. Clinically the disease presents itself as foci of subepithelial infiltrations that rarely ulcerate and consist predominantly of mononuclear elements; plasma cells are occasionally found in considerable number, especially about the periphery of the nodules; polymorphonuclear and giant cells are rare. An extensive clinical and bibliographic material is subjoined.

*Protein Picture of Blood and Ascitic Fluid in Atrophic Cirrhosis of Liver. D. Mircoli and M. Ferroni.—p. 193.

Studies on Permeability in Man of Kidneys by Dextrose: III. Effect of Adrenal Cortex Extract and Epinephrine. C. Bianchi.—p. 216.

Blood and Ascitic Fluid Protein in Cirrhosis.—Mircoli and Ferroni studied the relation between the protein levels of the blood and those of the ascitic fluid before and after paracentesis in cases of atrophic cirrhosis of the liver. Their observations of the modifications of protein levels included those of the albumin and globulin content and were based on more than 100 biochemical assays carried out during two to eight months on four cirrhotic patients. Total blood protein levels maintained a notable constancy throughout the course of the disease; however, initial and final levels hovered near the lowest normal limits. In the final stages of the disease with marked hepatic insufficiency the protein levels did not vary from those initially observed. Only a moderate reduction in the protein content of the blood was caused by the withdrawal of ascitic fluid in the majority of cases. Restoration of previous levels usually occurred within a week. The effect of paracentesis on the albumin and globulin fractions was to reduce, at first, the albumin content and to increase the globulin content. Total protein levels of the ascitic fluid behaved differently from those of the blood, showing a decrease after paracentesis. In general, high globulin levels in the blood were associated with high globulin levels of the ascitic fluid, both before and after paracentesis. In the great majority of tests of the protein quotients of the ascitic fluid, a clear tendency was exhibited by the globulins to predominate over the albumins. The effect of paracentesis on the protein quotients of the ascitic fluid was to increase it more often than to decrease it. The authors question the significance attached to the function of the liver in the production of blood proteins in general and of albumins and globulins in particular. They base their doubts on the observations that, even in late stages of atrophic cirrhosis of the liver in which decided hepatic insufficiency has occurred, almost unchanged blood protein levels are encountered.

*Postoperative Adrenal Insufficiency. A. Lucena, A. Peregrino,

C. Ramos and N. Bethlem.—p. 123.

Ether Soluble Protein in Serum of Patients with Neoplasms.—Their previous isolation of an ether-soluble substance from the serum of cancer patients for the diagnosis of carcinoma (nineteen cases analyzed) was confirmed by Carlos and José Esculies, using a revised technic that employed T. B. Robertson's microrefractometric method for serum analysis of minute globulin and albumin percentages in the blood serum. Observations of carcinomatous and other patients after total extirpation of the tumor growth had shown that reactions, previously positive, had become negative. This was not true for partial extirpation. The ether-soluble substance isolated is regarded by the authors as of protein nature and is susceptible of precipitation by sodium sulfosalicylate. Further observations directed to the albumin and globulin fractions of the protein disclosed that the reactive property resided in the globulins but only as vectors of the ether-soluble protein, not as substances independently capable of eliciting positive response, though hyperglobulinemia was regularly found in all serums. This ether-soluble protein in cancer patients may either be the product of an abnormal metabolism of the cancer cells vitiating normal protein metabolism or a protective ferment called into being against the invasion of abnormally metabolized protein derivatives. Both interpretations are correlated with the observations of previous investigators. The problem of establishing whether the protein isolated by the authors possesses fermenting activity in the presence of the same serum from which it is extracted as well as that of determining the precise polarimetric deviation requires further investigation.

Postoperative Adrenal Insufficiency.—Lucena and his associates investigated the effect of surgical intervention on the activity of the adrenal glands in twenty-three cases, five of which presented a grave clinical picture, from the point of view of the modifications of sodium and potassium levels of the blood. Basing their biochemical calculations on a normal standard of from 18 to 20 mg. per hundred cubic centimeters for potassium and from 320 to 340 mg. for sodium in the blood, they found clear evidence of postoperative upset of balances equivalent to adrenal insufficiency, entailing clinical manifestations of varying intensity, in every case. An abnormal ratio of both chemicals was ascertained in 85.7 per cent of the cases. In 10.7 per cent the potassium content was normal but the sodium levels had fallen below normal; on the other hand, in 3.6 per cent of the cases normal sodium levels were associated with an increased potassium count. Sixteen of eighteen cases examined (88.88 per cent) showed hypotension. The authors believe that every surgical intervention constitutes an invasion of the adrenal glands, capable of inducing a grave and even fatal insufficiency in serious and atypical cases.

*Tuberculous Bone Foci. G. Odelberg-Johnson.—p. 1084.

Tuberculous Bone Foci.—Odelberg-Johnson states that the tuberculous bone focus is a part symptom of tuberculous infection and that treatment must be directed against the general tuberculous disease. By local treatment in the form of operative and orthopedic intervention and long-continued fixation and elimination of weight bearing, local healing and maintenance of function can be attained in the best cases, especially when removal of the bone focus is possible. As a rule there is healing with limited function. Sometimes the process continues in spite of general and local treatment. The author emphasizes the importance of carrying out major operative or orthopedic measures when the general condition is optimal and the activity of the tuberculous infection is minimal, while on the other hand treatment must not be so conservative that the indicated intervention is delayed too long.

PSYCHOTIC AND SOMATIC INTERRELATIONS

WILLIAM F. PETERSEN, M.D.

CHICAGO

AND

HANS H. REESE, M.D.

MADISON, WIS.

It is curious that the appreciation of the interrelation of mental and biochemical rhythm has been so long delayed. Now it would seem that almost overnight "psychobiology" has been achieved although actually Adolf Meyer has been devoted for years "to the reactions of the unitary organism and the study of man as a person."

There have been at least two impediments: First, the biochemist has shunned long time observations on the human subject, although Otto Folin some thirty-five years ago¹ pointed out the absolute necessity of such an approach.

The biochemist, usually studying single samples of blood from presumably "normal" persons, has set up a series of so-called normal standards, quite overlooking the fact that even normal persons, when studied over long periods, may reveal deviations of considerable magnitude—not only in such basic values as the p_H , the carbon dioxide content and the chloride concentration of the blood but in the values for calcium, potassium, sugar or cholesterol.

The biochemical study of the psychotic patient is essentially a dynamic, not a static, problem—it involves evaluation of levels that may be critical for the individual under observation, even though they lie within the statistically "normal" range.

Second, the psychiatrist is preoccupied with the intangibles of psychopathology, of psychosomatics and of psychoanalysis and with the relative details of miscellaneous social and domestic environmental factors that presumably might shed light on psychic reaction.

We will begin by stressing the fact that the psychotic person lives in an atmosphere and that atmospheric environment in this region of the world varies tremendously from day to day. Most psychiatrists are in agreement that the psychic " . . . the psychotic patient are very . . . the scene" environmental alterations of all kinds, that they are unusually unstable and readily fatigued organisms.

We will agree that the tissues of the central nervous system are most susceptible to change in oxygen ten-

sion. Combining these several lines of agreement, we might inquire whether the patient with a psychotic predisposition may not be unusually susceptible to changes in weather, because weather is concerned with oxygen supply. Weather provides the kind of air that one breathes.

It is impossible to enter into the detailed analysis of metabolic phase fluctuations in the space here available. Suffice it to say that every organism is constantly pendulating between poles of normality: (a) from increase in blood pressure, on the one hand, to decrease, on the other, (b) from a period of high metabolic rate to one of low, (c) from depressed oxidation or preponderant reduction to one of adequate oxidation and lessened reduction, (d) from dehydration to hydration and (e) from increased cellular permeability to decreased cellular permeability.²

MOODS IN THE NORMAL LEPTOSOMATIC AND PYKNIC

Practically every normal person is aware of occasional change in mood, the intangible and possibly subconscious perception or awareness either of somatic equilibrium or of departure from normal equilibrium in the direction of greater exhilaration and buoyancy or of depression (thymergasia), the feeling of inadequacy and futility (parergasia).

While the perfectly normal and well equilibrated person will reveal fewer swings in moods, the somatic variants in either direction (the pyknic and the leptosomatic type) are less stable, and in these groups one finds a distinct increase in the number of persons who reveal more marked shifts in mood. During youth the pyknic individual is usually very stable but occasionally has periods of behavioristic disorders;² in the leptosome periods of elation or depression, particularly depression, are more common.

The moods can be identified with a shift in blood chemistry. In general the pyknic individual does not experience change in mood with periods of greater acidity, i. e. lower p_H . However, with periods of increased alkalinity there frequently is associated the feeling of greater energy, restlessness and exuberance. Then may follow irritation, explosive anger, temper tantrums, and the like.

The leptosome reveals less reaction to a swing in the alkaline direction. An increase in the p_H of the blood does not bring about much of a shift toward a feeling of buoyancy. Periods of decrease in the p_H are definitely associated with "blueness," depression and finally irritability in many persons of this type.³

Read before the Section on Nervous and Mental Diseases at the Ninety-First Annual Session of the American Medical Association, New York, June 12, 1940.

3. Similar pendulations of rhythm in many of the other blood constituents and physiologic mechanisms have been determined (Petersen and Milliken²).

If change in weather can affect the blood chemistry so profoundly, may it not be expected that the abnormal psychobiologic status may at times shift to normal or a phase of quiescence and relative adjustment or that disturbance and a psychopathologic state may be precipitated by meteorologic disturbances?

WEATHER CONDITIONING OF THE PSYCHOTIC STATE

In order that our study may be wholly free from personal selection or bias, we turn to the first American day by day study of changes in the psychotic patient, with coincidental clinical vascular and blood cytologic studies, published by Dr. Francis M. Barnes Jr. in 1909.⁴

As the observations are dated and graphed, they afford an opportunity of immediately associating the clinical and laboratory studies with the meteorologic conditions of the time.

In chart 1, Dr. Barnes's graph is subtended below a meteorogram of Baltimore for the period concerned. Characteristic psychic alterations, with periods from the beginning of the disturbance to recovery, are indicated on the Barnes graph by black bars, which are numbered from 1 to 7. While Barnes observed the rather characteristic psychotic change and associated mental alterations and cited some laboratory observations, we are here interested only in the dated mental changes associated with the precipitation of the acute attack.

An excerpt from Barnes's case record follows:

"CASE 1.—No. 541, male, aged 46.

"*Anamnesis.*—One brother and one sister are characterized as 'neurotic,' and one sister developed a psychosis from which she did not recover; otherwise, the history is unimportant. No alcoholic or drug addictions. . . . As a child he had some mild convulsive attacks, and in boyhood there was a trifling head trauma.

"The first mental attack occurred about 1890, when he was twenty-eight or nine years old.

"1900.—Since his last admission, the attacks have become more frequent and of shorter duration. At the onset, there is

Chart 1.—Barnes's curve of observations in case 1. The heavy black lines represent periods when the patient was passing through an attack—"abnormal" days. These are numbered from 1 to 7. The curves for temperature, pulse rate, blood pressure, respiratory rate, red blood cell count, hemoglobin and white blood cell count follow, in the order given. After Feb. 21, 1908, the observations are dated. The meteorogram for Baltimore has been superimposed. It indicates daily maximum and minimum temperatures, as well as barometric pressures. Note that periods of increase in barometric pressure precede the onset of attacks.

noted motor-restlessness, insomnia, irritability, inaccessibility and irrelevance. The excitement rapidly reaches its height, and auditory and visual hallucinations are present. During this time he is careless in person and habits. The attacks

average now, from five to six weeks in duration. The only change is the appearance recently, of short periods of mutism, posing, etc., in an otherwise excited day.

"*Present Condition.*—On reviewing the condition for the past year, one finds that the changes which have taken place have been those of detail only. As a general rule, the patient exhibits no prodromal signs by which the beginning of an 'abnormal' period can be detected. Occasionally for a period of from twenty-four to forty-eight hours he may appear drowsy and disinterested in his usual pastimes. The onset may occur in either one of two ways: after a night's

Chart 2.—Baltimore meteorogram with periods of attacks in Barnes's case 1, indicated by black bars. The mean barometric pressure for the seven episodes is indicated in the graph below the meteorogram for the ten days preceding the attack, the day of the onset and the following nine days, and the ten days following the attack.

undisturbed sleep, he may awake mute and resistive; later in the day this mutism may be interrupted by a psychic elevation with marked logorrhea, irrelevancy in answers and inaccessibility, with slight distractibility, which condition, however, is soon replaced by the former one of mutism and resistiveness. The most common onset is that with mild excitement which persists for several hours and is replaced by a mute, resistive phase. During the excited phase he is quite inaccessible; attention is poor or wanting and there is but little distractibility or divertibility; association is rapid but imperfect. Occasionally one may get a reply to questions, but the replies are irrelevant in the extreme. Irritability is often marked; logorrhea is continuous, the stimulus apparently is mostly internal, but at times the trend of thought is obviously influenced by outside events.

"The average course of an attack varies somewhat. As a general rule, after a few hours of mild excitement there follows a period of from five to ten days' duration during which he will remain in bed, mute and resistive. Occasionally during this period a condition of mild excitement will return for transient intervals. During the first few days he is untidy in person."

The seven abrupt psychic changes illustrated in the graph began on Oct. 3, Nov. 4 and Dec. 7, 1907, and on Jan. 13, Feb. 11, March 5 and April 3, 1908.

When studies were made with sufficient frequency, as toward the end of the period, it is noted from Barnes's graph that each episode was associated with an increase in leukocytes and in temperature, pulse rate and respiratory rate, as well as in blood pressure (the last change is observed in characteristic fashion in the fifth and sixth episodes).

A careful examination of the meteorologic temperatures and barometric pressures which have been superimposed above the Barnes graph reveals a rather characteristic meteorologic situation, namely a period of cold and high barometric pressure that existed before the change in the clinical status. The mean barometric pressure for the ten days preceding the attack, for the day of the attack and the following nine days and for the following ten days is shown in chart 2. Here the seven attacks are indicated by black bars below the meteorogram, and the mean barometric pressure is indicated on the graph below.⁵

4. Barnes, F. M., Jr.: A Clinical Study with Blood Examination of Two Atypical Cases Related to the Dementia Praecox Group, *Am. J. Insan.* 65: 559, 1909. The cases studied by Barnes are similar to those studied by Gjessing (*Beiträge zur Kenntnis der Pathophysiologie des katatonen Stupors*, *Arch. f. Psychiat.* 96: 319, 1932).

5. Because of the small number of dated attacks here available a statistical analysis is of little value; nevertheless, the probability of such a situation occurring by chance is but 1:10. The usual level of significance taken for discarding a negative hypothesis is 1:20; however, when one considers the nature of the problem, the probability of 1:10 may be sufficiently small to conclude that the movement of the barometer is an important contributing factor in the dating of the attacks.

An increase in barometric pressure of the magnitude here involved indicates that a cold air mass passed over the region and this was in turn followed by the passage of a cyclonic (warm) air mass of more than usual severity. An unusual environmental situation is effective in producing an unusual biologic (and psychic) reaction.

It is this shift that results in the characteristic behavior of the patient—first a period of stimulation and restlessness, followed by stupor. The diversion of biologic phase pendulation we have described as the ARS phase and the COD phase to indicate (1) a period of relative anoxia in the peripheral tissues of the central nervous system and (2) a period of compensation.

After this unusual phase of stimulation and fatigue, a certain amount of time is required for the psychic state to become relatively stable and normal. After this state has been reached the recovery period lasts for a variable time, during which the patient is relatively resistant to environmental swings.

When one compares the shifting moods of the normal young pyknic with those of the leptosome and relates them to the biochemical status of the time and to the weather, it is noted that the leptosome is more apt to become "blue," moody and finally irritable after periods of cold (actual or relative), i. e., the metabolic status is one of lowered p_{H_2} , low blood pressure and low blood sugar (COD phase). It corresponds to biologic overstimulation or fatigue.

The pyknic individual is relatively indifferent to this status but becomes buoyant, energetic, restless and ultimately irritable, with periods of increase in p_{H_2} , most often associated with the passage of a polar front. At that time an increase in blood pressure and blood sugar and a relatively high potassium calcium ratio exist. The cerebral tissues are functioning under conditions of relative anoxia, demonstrable in the peripheral and pelvic vascular beds.

These associations in the normal person are related to the characteristic psychic manifestations in the schizophrenic and the manic-depressive patient and account for the fact that the schizophrenic (slender!) type is often more activated in the spring (relative spring acidity!) and the manic-depressive (broad!) in the summer and autumn (period of relative alkalinity), as demonstrated in admission records in all state hospitals.

ACUTE EPISODES: WEATHER AND THE MENSTRUAL CYCLE

Barnes's second patient was a woman. In this case one is immediately faced with the biologic phase interference caused by the menstrual cycle,^{2a} which, in its various components, may amplify or negate the biochemical swings and incidental reactions induced by the meteorologic situation. As a result, the ultimate biologic and psychic reactions become much more complicated.

A part of Barnes's description of the case follows:

"CASE 2.—No. 547, female, aged 43.

"*Anamnesis*.—One sister died of tubercular meningitis; a paternal uncle was insane, and a maternal aunt has for a number of years been invalided with hysterical paralysis. There was no consanguinity, no history of alcoholic or drug addictions. History of the patient's early life is unimportant; there were no convulsions during childhood or later. She obtained a college education and was a good student. Since about sixteen years of age, at which time her mother died, she has been rather melancholic and of a depressed disposition, more reserved and quiet than formerly. Menstrual function was normal in

all respects until 1890, at the age of twenty-five, when she received a severe fall from a horse; since then there has been considerable irregularity in time, associated with pains, headache, etc.

"The first evidence of the present psychosis appeared in 1892, following the prolonged nursing of her sister. She became restless and irritable; at first would take no rest and then became insomnolent; was auto-accusatory (had neglected her sister) and attempted suicide. There were delusions of persecution, and both auditory and visual hallucinations. When she was admitted to this hospital in 1898 it was learned that since 1892 she had repeated attacks at intervals of from two to three weeks and of from two to three weeks' duration. These have all been of a similar nature. More recently they have become more intense and violent, occurring at still more frequent intervals and lasting for shorter periods. Excitement is the most prominent feature during the attacks, when, at its height, she is violent and homicidal. A brief period of depression (apathy and inertia) may either precede or follow the excited phase; in the intervals she seems quite well.

"*Present Condition*.—There has been some change in the course of the attacks, as will be seen from a comparison of her condition in 1902 with that of 1908. Formerly, there was little evidence of the stupor which is now so marked. At the onset, which is sudden, abrupt and unheralded, occurring in the early

Chart 3.—Barnes's curve for patient 2, studied from Oct. 7, 1907, to March 10, 1908. A meteorogram for Baltimore, showing the daily maximum and minimum temperatures as well as the barometric pressures for this period, is superimposed above the clinical observations. The clinical curves indicate temperature, pulse rate, blood pressure, red cell count, respiratory rate, hemoglobin and white cell count. Periods of attack are indicated by black bars at the bottom and are numbered from 1 to 5. Menstrual periods are represented by the black bars over the patient's temperature curve. Circled numbers indicate the following: (1) end of a period of disturbance; (2) beginning of attack 1; (3) transient quiescence; (4) end of attack; (5) beginning of attack 2; (6) end of attack; (7) beginning of attack 3; (8) (9) and (10) days of quiescence; (11) beginning of attack 4; (12) end of attack, and (13) beginning of attack 5.

morning usually, there is wild psychomotor excitement; this after a few days gives way to a mixed state of alternating excitement and stupor, which is, in turn, replaced by a condition of stupor of varying intensity, from which she emerges to her 'normal' state."

It has been seen that the same meteorologic event initiated the onset of the second attack in case 1.

In Barnes's larger graph (chart 3), covering the observation of this patient from October 1907 to March 1908, five distinct periods are represented. An analysis of the blood pressure levels before the attack revealed a situation similar to that in case 1. During period 3 it will be noted that on three days, indicated by 8, 9 and 10, transient remissions occurred; each was distinctly associated with the passing of polar air masses.

When, as in the previous case, one examines the meteorologic association of the onsets of the attacks, one notes that attack 1 began after a period of increased

barometric pressure and falling temperature. Attack 2 occurred with decreasing temperature and rising barometric pressure; attack 3 after a period of increased barometric pressure; attack 4 in association with a barometric crest and falling temperature, and attack 5 with a characteristic polar front of considerable magnitude.

The average barometric pressure for the ten days before the attack, the first ten days after the beginning of the attack and the ten days following the attack again makes evident the fact that a period of cold (increased barometric pressure) was associated with the onset of the episode (chart 4).

When transient interruption of the stupor phase occurs, as at 3 and 8, 9 and 10 in chart 3, one finds either a menstrual period or a period of unusual meteorologic activity, i. e., a sharp polar episode, in temporal relation to the change in psychic status.

No forces in the environment are of greater significance in conditioning the swing in the moods of the normal person and the change in the psychic status of the psychotic patient than those that are grouped under the term "weather."

The air mass in which the individual exists fluctuates from the extremes of the dry, cold, clear polar front to the moist, turbid, warm and relatively light tropical mass. Life in this region of the world requires constant physical adjustment to a continually changing situation presented by the turbulence of circulation of the air masses.

The passage of a polar front initiates a series of physiologic alterations designed to insulate the organism. Incidental thereto is transient blood alkalosis,

Chart 4.—Mean barometric pressure for the ten days before the onset, the first ten days of the attack and the last ten days of the five episodes recorded in Barnes's case 2. Note the increased barometric pressure associated with the onset of disturbance.

increase in blood pressure and relative tissue anoxia in the peripheral tissues, the cortex of the brain, the pelvic region and, under some circumstances, the myocardium. In the person with a manic-depressive psychosis this biochemical and endocrine reorientation frequently initiates a hypomanic attack.

This reaction is followed by a compensatory period, with relative acidity, a fall in the blood pressure level and low blood sugar and potassium calcium ratio, and generally with an increase in the basal metabolic rate and capillary permeability. In the normal person this period of stimulation may lead to actual biologic fatigue. In the schizophrenic person it is this phase that is most often associated with evidence of restlessness, excitement and abrupt changes in behavior, which are expressed in various ways.

As repeated weather episodes make up the total picture that is termed season, it becomes evident that the schizophrenic patient is more often disturbed during a period in which the general p_H levels are low—a situation occurring most often in the late winter and spring. By contrast, the manic-depressive person finds it more difficult to adjust in periods of relatively high p_H levels, and these are more apt to occur in the summer and autumn.

CONCLUSION

As far as the biochemical rhythm of any individual is conditioned by the environmental situation, both the moods of the normal person and the shifting psychic picture of the psychotic patient reflect, in varying degree, the change in weather, modified, of course, by many other forces, such as the sexual cycle, physical and mental activity, diet, infection, trauma and emotional situation. The effects of weather are most significant because they are relatively prolonged and inescapable, even when the patient is quiet and in bed (though naturally they are then modified), and reveal summation phenomena that are particularly significant in this geographic region, where frequency of change is characteristic and outstanding.

Weather will bring into relief latent hereditary dispositional and constitutional tendencies in the general psychopathic population. Loosely constructed paranoid, delusional effects or vague hallucinatory experiences may become vivid dissociations with schizoid regressions, or emotional instability swings may be augmented into a phasic manic-depressive psychosis.

Meteorologic changes will affect the never static biochemical rhythm, leading to faulty oxidative and metabolic disturbances, which, in their sequence, are mirrored in psychopathologic phenomena.

ABSTRACT OF DISCUSSION

DR. LLOYD H. ZIEGLER, Wauwatosa, Wis.: This paper, correlating abrupt weather changes with exacerbations of psychotic behavior, is interesting. The arthritic are proverbially sensitive to weather changes. The mechanism of this has not been clear. We have all observed that heat, 90 F. and above, together with humidity near the saturation point, is a devitalizing condition inimical to activity and thought. The behavior of some aviators is affected by quick changes in barometric pressures corresponding to altitudes. Caisson disease belongs here too. Some diseases appear to have a seasonal incidence, for example poliomyelitis. Psychoses may obey this law to some extent, but about this much needs to be learned. The migration of birds and the hibernation of certain animals is closely related to changes in the weather. A superb example of the effect of climate in modifying animals is to be seen at the Grand Canyon of the Colorado River. The south rim is about 7,000 feet above sea level. The north rim is about 9,000 feet, and the river and canyon have kept animals that cannot fly apart for countless years. Except for a difference in temperature, the climate of the two rims is essentially the same, and this one difference reflects itself in the animals of the same species by a variation in color, size and other qualities. Their behavior is affected as well as their morphology. One cannot deny that sudden weather changes tend to modify behavior. However, such environmental changes in themselves are not sufficient to account for the genesis of a psychosis. There must be another factor that correlates with the development of a psychosis more than the weather; thus far it has defied research, except that components of it may be exemplified in brain injuries and anomalies of development. Dr. Petersen has made extensive investigations to ascertain the effect of weather changes on disease and biochemical states of various kinds. It is well known that some people are conditioned, in the pavlovian sense, by unpleasant experiences so that the season or the weather at the moment serves thereafter as the stimulus to bring about a recurrence of the feelings associated with the original experience. Weather is one great environmental influence that is common to large groups of people. In time such studies may enable Drs. Petersen and Reese to classify people with regard to some degrees and qualities of sensitiveness, which could well be the earliest indications of a latent psychosis.

DR. IRVING J. SANDS, Brooklyn: The authors have emphasized the influence of the weather and barometric incidences and climateric situations on behavior disorders. They have

vindicated theories which the older clinicians discussed and which led to the coining of the term lunacy—the influence of the moon on human behavior. In the pioneer days of scientific psychiatry, study was limited to observations of a few clinical or pathologic manifestations. Today the human being is regarded as a total personality, as a behavior organism in which every part of his constitution participates in his reaction to situations. All observers now realize the importance of regarding the human being as a whole. We are indebted to the authors for once again directing attention to a most important subject.

DR. HANS H. REESE, Madison, Wis.: It is not easy to correlate all the weather factors which Dr. Ziegler mentioned; they make the picture too complicated. The best way is to consider only the daily mean temperature alterations and the changes in the barometric pressure. These studies support our assumption that the human being is like a cosmic resonator to his surrounding regional meteorologic environment. We postulate that the "feeling" for the barometer is conditioned by rhythmic swings in our constantly fluctuating biochemical milieu, which in the topic under discussion mirrors itself in psychopathologic reactions and psychiatric episodes. The great variability, from simple inadequate feelings and moods to extreme clinical poles of manic-depressive, schizophrenic or paranoid reactions, is related, in our opinion, to inherent genotypic deficiencies in the psychobiology of the individual. A psychic trauma, of whatever origin it may be, upsets the biochemical requisite which is necessary for increased or lessened cellular activity and subsequent functions. The well buffered person with a wide range between the poles of adjustment and of inadequacy is harmoniously integrated, he meets wear and stress situations, psychic trauma and meteorologic bouts well, because his body functions can adjust themselves readily. However, the constitutionally inadequate person with inherent genotypic deficiency will present symptoms depending entirely on the organ selectivity, which cannot make adjustments to abruptly occurring physicochemical changes. The question of adequate and inadequate oxidation in cells and tissues is the important explanation to psychic and psychiatric disorders. This is weather linked, biochemically measurable and clinically obvious. We have analyzed the excellent dated material of R. Gjessing of the University of Oslo and of K. F. Scheid of the University of Munich. We have made graphs of the meteorology of the time for Oslo and Munich, and we could study the interrelation that may be apparent. Gjessing and Scheid's material reveals that the onset of acute episodes in their cases began with a barometric crest and with a period of lowered environmental temperatures. Therefore the weather events could clarify the otherwise obscure occurrence of excitement, stupor and febrile attacks in their cases. Dr. Petersen has pointed out that the onset of psychic or psychiatric episodes coincides with definite changes in the meteorologic environment. Febrile psychotic episodes are clearly related to weather changes. We are not assuming that meteorologic "catastrophes" are the cause of nervous and mental diseases, but we are certain that the "weather" is sufficient to tip a fluctuating unstable predisposed individual into any form of mental illness.

Insect Immigrants Banned.—There are still at large in the world some 20,000 kinds or species of insect pests which have not yet been found in the United States. Many have a great capacity for harm. The federal plant quarantines have halted at our shores thousands of these new crop threats. However harmless an insect is at home, it may be far from harmless in a new environment. For example, natural enemies—parasites and predators—keep the Japanese beetle from being economically important in the Far East. It reached the United States without these natural enemies, however, and found none here to check its multiplication. In the United States the damage by this insect now amounts to nearly if not quite a million dollars a year and it is still spreading. Plant quarantines forbid unconditionally any entry into the United States of certain fruits and vegetables, such as mangoes, yams, avocados, oranges, sweet limes and grapefruit, from certain countries, mainly those to the south.—Clip Sheet, U. S. Department of Agriculture, Oct. 20, 1940.

THE DETERMINATION OF PHYSICAL FITNESS

HENRY H. KESSLER, M.D., PH.D.

NEWARK, N. J.

Among the many problems that will be given serious consideration in the program of medical preparedness will be that of physical fitness; physical fitness of the soldier to perform military service and physical fitness of the worker to perform useful productive and continuous work. That this matter is of importance can be seen in the recent press report which expressed the concern of the Army Medical Corps about the physical condition of many applicants for army service. At least 30 per cent have been rejected in the New York area because of bad teeth, poor vision, flat feet, bad hearing and other causes.¹ Such a high percentage of rejections would seem to indicate indeed a low state of physical fitness of the general population or too rigid a set of minimum requirements for acceptance.

Physical fitness has been previously studied in respect to both military and industrial activity. However, it may be desirable to reconsider the problem in view of the present crisis and reexamine some of our past ideas concerning physical fitness because of the newer evidence which seems to dispute the validity of these ideas.

False concepts of capacity to work have had an important influence on our civil, industrial and military life. They have created vague standards of physical fitness that have condemned the physically defective, handicapped by minor disabilities but possessing great potentialities for functional performance. They have been influential in setting an arbitrary industrial age deadline of 40 for the physically useful individual. They have given excessive weight to psychologic and aptitude tests for determining physical fitness, while human energy and capacity have in general been largely underestimated.

These confused ideas play an important role in our national life, since they form the basis of much of our social and labor legislation. The restrictions of hours of work and the restrictions imposed on the labor of women and children are based on presumptions of limitations of physiologic capacity to work. These physiologic criteria are frequently cloaked with social and ethical values so as to identify the violation of or the deviation from the physiologic fact with sin. So, too, the evaluation of permanent disability in workmen's compensation has no scientific foundation but relies on actuarial and legalistic criteria for its determination, even though these methods are employed by physicians. Furthermore, the value of preemployment examinations in the selection of employees and that of the periodic physical examination in the maintenance of physical fitness in the industrial worker will be largely lost if the concept of physical fitness is not clarified in the light of newer information.

DEFINITION

Physical fitness may be defined in several ways. It may be considered subjectively as a state of being, in which case it would be described as normal, healthy, efficient, free from symptoms, free from gross physical defects, ability to withstand physical effort and strain, having the capacity to work. Again it may be defined in terms of its objectives: physically fit for what? Work, play, industry, military service? In a naval

1. Leone, G. E.: Causes for Rejection for Entrance into the Regular Army Due to Physical Defects, *J. A. M. A.* 115:1283 (Oct. 12) 1940.

military sense physical fitness may be defined as "keeping as many men at as many guns as possible." In its common usage, physical fitness is considered as a combined concept in which both subjective and objective elements play a part. In any case, it is almost automatically identified with three types of states: (1) ideal or superior, (2) normal or average, (3) substandard or inferior. For the most part the basis of this classification is a vague psychosocial concept of the normal person.

CONCEPT OF NORMAL

Physical perfection is recognized as an ideal or superior state, one which few people can achieve. The normal state is one which is free from obvious physical defects. On the latter basis it is virtually impossible to find a completely normal individual. This fact has been determined by physical examinations made in the army and by mass preemployment examinations as well as by studies of school children. In a study that I made of 6,565 male and female workers, only 7 per cent were found to be free from gross defects detectable by physical examinations, 70 per cent had minor defects, 16 per cent had advanced minor defects and 7 per cent had major defects.²

Nor does freedom from symptoms constitute a proper basis for defining the normal person. Autopsy reports frequently establish the fact that many individuals who have never suffered any subjective symptoms or physical signs of disease may present evidence of advanced cardiovascular disease, tuberculosis or other serious systemic diseases.

No matter what attempts are made to evaluate standards of physical fitness, social judgments generally complicate the point of view. The term normal, therefore, implies a personal judgment in which we use ourselves as the standard and the subject of our attention as the deviation from that standard. It represents, therefore, a series of physical and psychologic traits, the evaluation of which is influenced by social prejudices and attitudes.

SUBSTANDARD OR PHYSICALLY UNFIT

The presence of physical defects is frequently presumed to imply limitation of capacity to work. This premise may be true in some cases, but it is false in the majority of instances. Even in the presence of a serious physical defect, sufficient function may remain to carry on required industrial activity. Anderson's study³ of more than 4,000 physically handicapped individuals engaged in 635 different types of work shows the versatility of these individuals as well as the fallacy of thinking that because a man is physically handicapped he is functionally handicapped. The studies of the Western Electric Company⁴ covering a group of 685 men and women with physical defects show that the handicapped workers were as fully productive and showed no greater loss of time for sickness, accidents or personal reasons. In a study made by the Swiss National Accident Insurance Fund⁵ for the period 1930-1934 95,000 accidents were analyzed for the purpose of determining the influence of age on the frequency and cause of industrial accidents. The highest accident frequency was seen in the age groups 20 to 24 and 25 to 29, the ratio being 216 and 218 respec-

tively per thousand years of life exposure to accident risks. For workers from 40 to 44 the frequency rate dropped to 162 and for those from 45 to 49 to 148 per thousand years' exposure.

In the state of Connecticut⁶ more than 8,000 waivers have been signed by those suffering from physical defect of various sorts. The accident frequency rate in this group has been no higher than in the group which signed no waivers.

THE SAFETY FACTOR

The long list of outstanding characters in history, including the fields of literature, art, politics and military and industrial activity, illustrates the point that a disabled person may not only be normally productive but may actually excel in a chosen field.⁷ The ability of individuals with physical defects to be as fully productive as so-called normal individuals, that is those free from physical defects, is due largely to the safety factor.

The body can accommodate itself to unusual demands, despite disease or congenital or acquired defects, through physiologic resistance based on factors of safety in its own structure. Through self repair, regeneration, hypertrophy, adaptation to new conditions, vicariousness of function or substitution of one structure for another such as the skin for the kidney, the body is able to combat its environment and fight off harmful influences.⁸

The organic defect may even act as a stimulus to overcompensation of the total personality. Adler⁹ developed a complete system of psychology based on this idea of organ inferiority. He stated that we are equipped with materials that are rarely fully developed. Yet with this imperfect development good performances are turned out, just as our ancestors produced great works with imperfect tools. It is probable that a man equipped with defective organs, that is, with inadequate tools, will actually develop a better technic to combat the rigors of his environment. He will pay a great deal of attention to detail, devise more unerring shortcuts or may undergo a more intensive training.

OBJECTIVE CRITERIA OF PHYSICAL FITNESS

Viewed objectively, physical fitness may be regarded as the ability to perform productive and continuous work. The productive capacities of an individual may be said to depend on (1) native ability, (2) training and (3) the presence or absence of illness.

APTITUDE

Native ability or aptitude has been considered the key to the whole problem of physical fitness by educators, employers and personnel men who have devised various tests for the determination of these aptitudes. It is presumed that employees can be selected who will be most productive and least accident and sickness prone by testing them for such traits as concentration, observation, imagination, strength, endurance, speed, dexterity, quick grasp, kinesthetic discrimination, judgment and intelligence. Interest in these tests has been so popular that a bill¹⁰ has been introduced in the United States Senate for the purpose of providing means for the determination of physical fitness and aptitudes. By these tests it is hoped to determine what capacities the individual possesses or to what extent he possesses an unusual trait, talent or ability.

CLASSIFICATION OF TESTS

Anatomic.—It would seem foolish to cast horoscopes on the basis of imaginary relations between physical development and capacity to work. Yet anthropologists and anatomists have used the form of the individual as a basis for classifying individuals for work. The relationship between the height when seated to the total stature, termed the thoracic coefficient, and the relationship between the weight and height of an individual, termed the morphologic coefficient, has been suggested by Amar¹¹ as a guide to the choice of workers fitted for a particular form of labor. Yet he admits that the formation of the body as an index is far from absolute, since adaptation is a factor of greatest importance. He mentions the fencer Kirschoffer, who did wonders despite his small stature. Amar divides individuals into four physical types, namely (1) the digestive type, (2) the muscular type, (3) the respiratory type and (4) the cerebral or nervous type. He implies correlative capacities for muscular and organic effort according to the specific physical type. Griffiths¹² describes twenty-four physical types in their adaptability to work. He details the work requirements for which these physical types may be adapted. Draper¹³ and others have also suggested the influence of constitutional physical make-up on the capacity for work. On the other hand, Harris¹⁴ does not agree that a high degree of correlation exists between physical development and physical efficiency. He believes there is no index of physical fitness or efficiency except the ability to do one's job and live to a ripe old age. The establishment of a false index will only produce inferiority complexes.

Physiologic.—From a scientific point of view, the capacity for work may be regarded as a mechanical concept and the human body as a machine capable of expending energy for the execution of certain work. Thus considered the useful mechanical work, the industrial effect, is a quantity which can generally be calculated without difficulty. The work done in ascending a mountain, a staircase or a ladder is the product of the weight of the body and the vertical height ascended. The work of a cyclist is the product of the distance covered and the passive resistance of rolling friction, and so on. The amount done by the arms and legs in operating tools or work done in locomotion can also be measured more or less exactly. However, this mechanical quantity is more difficult to measure when the movements are diverse and complicated because any static effort of the workman escapes the measurements, although the whole muscular activity consists of static efforts.

As a machine, the body is subject to the law of thermodynamics applicable to all machines. Every machine transforms energy. For example, the thermal energy of the coal in the boiler is transformed into electrical energy in the dynamo. In any motor the total expenditure of energy may be divided into the static expenditure needed to overcome the force of friction and the dynamic expenditure which corresponds to the useful work done. In inanimate machines the static expenditure is small compared to the dynamic expenditure, but this is not the case in the animal motor. The latter is always at pressure because if it ceased an instant

to be in that state life itself would be arrested. The static expenditure in the human motor is an active and permanent process because it is determined by physiologic needs. This difference between inanimate and animal machines is a factor which has been seriously overlooked by investigators who have interpreted the human body as a machine and who have established certain indexes of its function.

Estimates of physical fitness are frequently based on tests of muscular strength. Police departments use these tests frequently in determining the fitness of applicants for police duty. This factor may be measured by two methods, the ergographic and the dynamometric. In the first, following the classic method of Mosso, the arm or leg is made to perform a piece of work such as rotating a wheel by the hand or pushing a pedal with the leg. The work done is measured according to the mechanical formula the product of the force and the distance from which it is applied. The fallacy of this method is that it depends on fatigue as an index of the amount of work performed. Unfortunately there is no method by which fatigue can be measured. Lee¹⁵ has definitely shown that no test has been devised, be it chemical, physiologic or psychologic, that can measure fatigue.

The use of the spring dynamometer in the determination of physical strength is fraught with error because of the mechanical construction of these appliances. The force of single muscular contractions on deformable springs is used in tests of muscular efficiency. The grip dynamometers of Collins and Smedley are commonly employed. As tested in a large series of cases it was found that the size and shape of the hand, as well as the previous trade and experience, were more important than intrinsic muscular strength in the determination of the results.

The spring balance is a more accurate instrument in determining the muscle strength of individual muscle groups. However, muscular activity is a complicated act and the effectiveness of muscle action depends not only on intrinsic muscular strength but on neuromuscular activity as well. The effectiveness of the blow of a prize fighter will depend on strength plus split second timing and accurate localization of the target. These factors are the result of training. While it is conceivable that, in a single vocation, a job analysis can be made of the muscular strength requirements, it would be almost impossible to include the hundred and one auxiliary muscular acts accompanying specific tasks. Furthermore, these tests omit the important factor of adaptation and training in overcoming primary strength deficiencies.

Tests of cardiovascular efficiency have been frequently used to determine physical fitness. The pulse rate and blood pressure are taken before and after exercise and compared to arbitrary normals. It is assumed from these tests that the results represent the efficiency of the body in its adaptation to work. Schneider,¹⁶ Scott¹⁷ and Crampton¹⁸ have devised indexes of physical efficiency based on these factors. But these formulas are false since they do not evaluate the whole body but select and abstract only a small part of it. Furthermore, they fail to take into account the safety factor, while the

entire hypothesis underlying their use is based on the fallacious concept of man as a machine.

Spirometry has been used to determine pulmonary and cardiac efficiency.¹⁹ These vital capacity tests are also frequently employed in physical examinations in industry. In one lead plant, one of the main requirements for passing the physical fitness test on the part of applicants was a high vital capacity reading. It was assumed that such an individual would have a strong constitution and a strong resistance toward the development of lead poisoning. Nevertheless the incidence of lead poisoning was higher in the group with the high vital capacity reading, since the volume of inspired lead-containing dust was much greater in this group than in those with a lower vital capacity.

Psychologic.—Psychologic aptitude tests have received considerable attention in the measurement of intelligence and especially in the field of vocational guidance.²⁰ They have assumed such a popular acceptance transcending their real value that it has been difficult to avoid the accusation of phrenology, clairvoyance and fortune telling leveled at those engaged in this field.

There are many fallacies underlying their use: (1) the mechanical concept underlying these tests, namely, comparing the body to a machine; (2) the selection of comparatively few traits out of many thousands to represent the total physical and mental personality of the individual; (3) the difficulty in separating native ability from training, so that what is really being measured is a compound of the two; finally, and most important, (4) the assumption that there are great differences between individuals.

But do men really differ so enormously from one another as to place such great reliance on these tests? Do these differences, if they exist, obtain for the entire span of human capacities or are they encountered only in such special fields as, for example, those of mathematical or artistic ability or ability to pilot a plane? How much more productive is the most efficient individual than the least efficient in a given occupation?

Range of Human Capacities.—Many of the answers to these interrogatories have been provided by a study of the range of human capacities made by Wechsler.²¹ In this study are included the bulk of available data up to 1933, comprising studies of linear traits, body circumference, metabolic rates, physiologic functions, motor functions, and perceptual and intellectual abilities. Wechsler has shown that for the same age group there are little differences in human capacities. He has furthermore demonstrated that the total range ratio between the least productive and the most productive individual, as revealed by the existing available data, is not greater than 2 to 1. For example, in an industrial plant where disks were being strung this ratio was 2.12 to 1. In another operation, namely the speed of inserting bolts, the ratio was 2.09 to 1. In still another operation, that of card sorting, the ratio was 2.50 to 1. In the high jump the ratio was 2.01 to 1. In the broad jump the ratio was 2.07 to 1. In the upper limit of audibility the ratio was 2.09 to 1. These differences in performance are indeed small and are especially significant if it is remembered that they are a compound of native inherent ability and training.

TRAINING

Productivity depends not only on native ability but also on training. Much of the capacity which is being measured represents acquired knowledge, experience or actual instruction in general or special skills. While these may be measured, it must be understood that equal opportunity exists for the development of capacity to work based on training.

ILLNESS

I have already said that minor physical defects do not influence productivity. I am, of course, referring to static defects, as short stature, underweight, a stiff elbow, amputation of a finger or leg, leg shortening, or paralysis of a hand. Accommodation to these static defects may be sufficiently adequate to make the individual fully productive. The leg amputee can perform seated or standing work. Paralysis of an arm may still permit the individual to work as a draftsman or as a salesman.

Illness, however, is dynamic and not static. Tuberculosis, syphilis, arthritis or any infectious or degenerative systemic disease will affect productivity by influencing perceptual intellectual and motor functions. The detection of these illness states by complete and thorough physical examination is of definite and constructive value.

CONTINUITY OF WORK

Physical fitness depends not only on the capacity to be productive but also on the assumption that this productivity is not interrupted. Continuity is disturbed by loss of time. Absenteeism is important economically to industry and also to military service.

Loss of time is incurred because of so-called personal reasons, accident and illness. There is no way of protecting against loss of time because of personal reasons. Studies of accident proneness by the Industrial Fatigue Research Board have produced only equivocal results.²² Lanza and Vane²³ support the observation that sickness prone individuals exist. Although they constitute a small percentage of total employees they account for an inordinately large number of lost days due to illness. Lanza and Vane report that rigid standards of pre-employment physical examination are not the solution, since even in such highly selected groups as the military service noticeable degrees of absenteeism are encountered. There is, however, a high degree of correlation between sick absenteeism and the presence of serious organic illness or profound emotional instability. Hence complete and thorough physical examination will materially help to reduce lost time from these causes.

SUMMARY

Physical fitness is a socio-economic concept involving the social evaluation of a series of anthropologic, physiologic and psychologic traits. It becomes a medical concept in the presence of physical defect. Here the physician also derives a social judgment (ability to work) out of pathology. Pathology determines the nature of the illness or defect but not the extent of the remaining health or the extent of adaptation of the remaining functions. A person lives not only with his pathologic lesion but also with the remaining undisturbed organs and functions.

Physical fitness in its widest sense is the ability to perform productive and continuous work. This fitness is based on native ability, training and the presence or

absence of illness. The determination of these factors by physical examination is of limited value except as it may detect gross illness states or profound emotional instability, which are liable to influence productivity and continuity of industrial and military service. Static defects should be separated from illness states and their limited effect on working capacity properly evaluated. Rejection should be based on the presence of organic disease and not on static defects, except where job analysis in a specific vocation indicates unusual physical requirements. The popular notion that wide variations in individual capacities to work exist should be reconsidered in the light of Wechsler's data. Finally, in the determination of physical fitness by means of the physical examination, the physician should bear in mind that the average man can do the average job.

THE EFFECTS OF REPEATED ANOXIA ON THE BRAIN

A HISTOPATHOLOGIC STUDY

MELVIN W. THORNER, M.D.
Captain, Medical Corps Reserve, U. S. Army
RANDOLPH FIELD, TEXAS
AND
F. H. LEWY, M.D.
PHILADELPHIA

The effect of oxygen deprivation on the nervous system, and particularly the brain, has become a problem of great practical significance in recent years. The rapid progress of aeronautical engineering with the production of planes with high ceilings and rapid rates of climb has brought many of these problems to the fore. Another situation, only numerically less important, exists in the industrial and physiologic laboratory in which experimenters subject themselves repeatedly to conditions of oxygen lack. These two examples of repeated anoxia stimulated the initiation of the work reported here, in which an attempt was made to determine in guinea pigs and cats the nature and extent of the histopathologic changes which may occur in the brain after a single and after repeated periods of pure anoxia.

In order to function properly, the nervous system must have an adequate oxygen supply. There are several avenues open to explain this fact, and it is probable that no one approach alone is entirely adequate. One of these avenues is a consideration of the effects of oxygen lack on isolated parts of the nervous system. The effects of anoxia on small units of the nervous system have become known but recently. Lehmann¹ has shown that an excised nerve (which consists of the elongated processes of nerve cells) when deprived of its oxygen supply by immersion in an atmosphere of pure nitrogen demonstrates a typical sequence of irritability changes. This consists of an initial lowering of the threshold of excitability, followed by progressive failure of irritability of the nerve fibers. If the oxygen deprivation does not exceed certain time limitations, the nerve may be restored to its former functional state by allowing it access to oxygen. A similar succession of events in a natural situation was noted by Thorner and Brink² when the human ulnar nerve was deprived

of its circulation, which created, among other consequences, an anoxic state for a period not exceeding thirty minutes. The change in the functional state of the nerve, shown by the changes in threshold excitability, is reversible when the circulation has been restored. The synaptic junction of neurons is also deeply affected by oxygen deprivation. Bronk, Larrabee and Gaylor³ have shown that cutting off the oxygen supply to the stellate ganglion of the cat causes a progressive failure of the ability of the synaptic structures to transmit impulses. This effect too is reversible if the period of anoxia has not been too prolonged.

Similar functional changes have been observed in the central nervous system, as the spinal cord⁴ and brain. In these cases, either excitability or conductivity, or both, is taken as an index of the functional state. Gerard⁵ in a study of anoxia and neural metabolism, suggested that one of the functions of oxygen is to keep the cell membrane polarized and that complete anoxia initiates proteolytic processes in neurons. This reaction may occur partly as a result of accumulation of lactic acid in the anoxic state. Gellhorn⁶ believes that anoxia and hypoglycemia are very much alike in their physiologic effects as they act synergistically in the production of convulsive seizures.

A second avenue of approach to the problem of anoxia and the nervous system is the observation of the partial or total behavior of man and the intact or specially prepared experimental animal during oxygen lack. McFarland⁷ has made extensive psychologic studies into the general behavior of individuals breathing air in which the oxygen partial pressure has been reduced. Another opportunity in this type of study is provided by the present trend in the shock therapy treatment of schizophrenia by short periods of oxygen deprivation.⁸ Bentley⁹ approached the problem similarly. McFarland and others¹⁰ have confined their observations to changed reactions in circumscribed parts of the central nervous system, such as the central visual fields during anoxia and the ocular movements while reading. Jokl¹¹ has reported changes in the tendon reflexes during periods of anoxia. Most of these observations are concerned with the functional changes occurring during the anoxic period. Relatively little work aside from the observation of shock treated schizophrenic patients has been done with reference to the possibility of residual changes in the function of the nervous system as a whole after periods of anoxia. For the practical reasons cited in the opening paragraph, this is obviously worth investigation.

A third avenue of approach is the gross and histopathologic examination of the nervous system which

has experienced anoxia either alone or in combination with other factors. These morphologic studies yield evidence of structural change which, by inference, may be associated with functional change. It remains entirely possible that many sorts of functional disabilities may occur in which our present arbitrary methods of histopathologic technic may yield no valid information. The pathologic effects of cerebral anemia (which introduces other factors as well as reduction in oxygen supply) have been studied by Gildea and Cobb.¹² These authors found nonspecific cortical lesions such as focal areas of necrosis and both swollen and shrunken ganglion cells. The appearance of focal areas of true necrosis may require a lapse of twenty-four hours after an anemic period, but degenerative changes in the ganglion cells may occur almost immediately. The large and small ganglion cells were most sensitive. More recently Weinberger and the Gibbons¹³ produced a temporary period of anemia by occlusion of the pulmonary artery. They found permanent severe pathologic changes in the cerebral cortex of the cat after an anemic period of three minutes and ten seconds, while longer periods of occlusion of the pulmonary artery produced, in addition, lesions in the Purkinje cells of the cerebellum and in the nerve cells of the basal ganglions. Studies on ani-

rather than to the concomitant factors in anemia. Some of these factors have been indicated by Sugar and Gerard.¹⁴ In this group belong hypoglycemia, hypercapnia and disturbances of intracellular and extracellular ionic balance.

Fig. 1.—Section of brain cortex of guinea pig 9 immersed for fifteen seconds in nitrogen and decapitated thirty minutes later. This is a normal cortex showing normal architecture and well stained cells. (Cresyl violet stain; reduced from a photomicrograph with a magnification of 130 diameters.)

Fig. 2.—Section of brain cortex of guinea pig 10 immersed for thirty seconds in nitrogen and decapitated thirty minutes later. The nerve cells are insufficiently stained, the glia nuclei pyknotic. However, the damage is of metabolic rather than of structural nature, because silver impregnated slides show that the number of nerve cells is not visibly decreased. (Cresyl violet stain; reduced from a photomicrograph with a magnification of 130 diameters.)

Mechanical stoppage of the circulation to produce anemia has been supplanted by other methods. Crile and Dolley¹⁵ used pharmacologic methods to effect cardiac stoppage and resuscitation, while Batelli¹⁶ produced the same effects with electrical currents. The pathologic changes of the brain have been studied after various pharmacologic insults the main effects of which have been attributed to anoxia. Fatal cases of nitrous oxide-oxygen anesthesia have been described by Löwenberg, Waggoner and Zbinden,¹⁷ as well as by Courville.¹⁸

In these cases too in which death sometimes followed narcosis immediately, lesions of the cortex and basal ganglions predominate. These authors believe that anoxia is responsible for the changes observed. Carbon monoxide poisonings are of interest in this connection as they deprive the blood of its oxygen carrying capacity. Here again it may be questioned whether the

mals whose circulation is decreased introduce factors other than anoxia, and there is no evidence that the changes so produced may be due entirely to anoxia

cerebral changes in carbon monoxide intoxication are not caused in part at least by factors other than anoxia. In brief, we have found no record of investigations testing the influence of pure anoxia on morphologic changes in brain structures.

METHOD AND DATA

In order to study the effectiveness of anoxia without the introduction of complicating factors, it was decided to utilize the simple expedient of placing the experimental animals in an environment of practically pure nitrogen for various periods of time. The animals used were guinea pigs and cats. These were placed individually in containers with a glass top for observation. The containers could be flushed with a constant stream of nitrogen from a pressure tank. At the end of the period of immersion the animals could be removed and placed in the air. Since many of the animals became apneic during their immersion in nitrogen, artificial respiration had frequently to be used. It is a fortuitous fact that the heart beat continues and usually increases in rate both during these immersions and for minutes after an animal has become apneic. Because of the functional integrity of the circulation during these experiments, it may be stated that there is no significant factor other than anoxia introduced in these experiments. Of the

of the nervous system in anoxia when these secondary effects are excluded.

Guinea pigs immersed in an atmosphere of nitrogen behave in a somewhat stereotyped manner. There is usually an almost immediate increase in the respiratory

Fig. 3.—Section of brain cortex of guinea pig 11 immersed for sixty seconds in nitrogen and decapitated thirty minutes later. More extensive and intensive damage of the same type as in figure 2. Some large nerve cells in the deeper cortical layers are swollen, the nucleus is retracted and the cytoplasm is almost or completely unstained. The appearance of some nerve cells suggests permanent damage. (Cresyl violet stain; reduced from a photomicrograph with a magnification of 130 diameters.)

changes observed, many may be the result of factors which are secondary effects of anoxia, but the data apparently validly indicate the relation between structural brain damage and anoxia of the total animal. For this reason the results may not correspond to a synthetic picture derived from the study of isolated parts

Fig. 4.—Section of brain cortex of guinea pig 5 immersed twenty-four times in nitrogen. The animal died forty-eight hours after the last immersion. The difference between this cortex and that represented in figure 1 is striking. Although here is true what has been said in reference to figure 2, namely that many more cells are present than are stained with basic dyestuffs, a marked number of nerve cells are permanently damaged. Subpial hemorrhage. (Cresyl violet stain; reduced from a photomicrograph with a magnification of 130 diameters.)

rate. In from ten to fifteen seconds the animal becomes very active. In another twenty seconds the animal shows some arching of the neck and then slumps to the floor of the container. The retinal light reflex, ear, tongue and mucous membranes appear cyanotic. Spasmodic movements may be seen, varying from isolated clonic twitching to generalized convulsions. If the animal is immersed for more than one minute, it is usually apneic when removed and must be given artificial respiration. The majority of pigs immersed in nitrogen for 105 seconds cannot be revived. In no case did the heart beat cease before respiratory failure.

Cats immersed in nitrogen can be observed to exhibit the same symptoms, except that the time scale is longer.

The time required for recovery from anoxia varies with the length of the anoxic period and may extend over some hours in cats. In some animals death occurred directly from prolonged anoxia; in others death occurred many hours after seeming recovery from an anoxic period. A last group of animals was killed by decapitation after one or more anoxic periods. Many animals underwent repeated periods of anoxia. None of the animals developed unusual behavior or showed neurologic signs as a residuum. Complete gross and microscopic studies of the brain were made on all animals.

In general, the animals may fall into five groups:

GROUP 1.—*Animals rendered anoxic for various periods of time and decapitated within one-half hour of removal from the chamber.*

Animals (9, 10 and 11) kept for fifteen, thirty and sixty seconds, respectively, in nitrogen and decapitated thirty minutes later. The three animals were litter mates and albinos.

Fig. 5.—Section of fascia dentata of Ammon's horn of the animal decapitated after having been immersed in nitrogen for fifteen seconds, showing normal architecture and appearance of cells. (Cresyl violet stain; reduced from a photomicrograph with a magnification of 550 diameters.)

The brain of the animal immersed for only fifteen seconds seems to be normal (fig. 1). One is impressed by the great number of cortical nerve cells and their well stained appearance. There are some congested blood vessels and a few miliary hemorrhages over the cortex, but this plays a negligible role compared with the good preservation of cortex, Ammon's horn (fig. 5), cerebellum, basal ganglions and brain stem.

With longer immersion of the animals, the cell changes become slightly more marked, are patchy in distribution (fig. 2) and become more diffuse after sixty seconds of anoxia (fig. 3). Fresh perivascular hemorrhages are more frequent, and in the white matter perivascular areas of coagulation appear. The blood vessel wall is more darkly stained in some of them and not stained in others. In general there seems to be a tendency to increasing severity of tissue damage with prolonged time of immersion. However, the degree of damage cannot be judged from cresyl violet stained sections. Silver impregnation and hematoxylin show that the cell damage is of a chemical rather than of a structural nature. Many more cells are still in existence than take basic dyestuffs, though there is no doubt that some cells are permanently damaged with anoxia of sixty seconds' duration.

Conclusion.—Anoxia of fifteen seconds' duration does not produce visible damage to brain cells. Anoxia of thirty seconds' duration is followed by metabolic changes and anoxia of sixty seconds' also by morphologic changes in the cortical nerve cells. In the last group, in addition, subpial and intracerebral perivascular hemorrhages and coagulation were found.

These observations indicate that sublethal periods of oxygen deprivation produce damage to cortical cells, which becomes readily apparent if the animals are permitted to survive for one-half hour. The time of immersion in oxygen necessary to produce such changes is between fifteen and thirty seconds. Almost certainly many of these changes are reversible. In addition to the degenerative changes in cortical cells there are congestive and hemorrhagic blood vessel phenomena which appear even in the animal which was immersed in nitrogen for fifteen seconds. Presumably sufficient damage to the smaller units of the vascular tree may affect cerebral neurons as a secondary factor.

GROUP 2.—*Animals killed in nitrogen directly with no recovery period.*

One guinea pig (1) and one cat (7) killed in nitrogen directly.

These animals show subpial hemorrhages and some vague nerve cell changes. The cortical architecture is normal, as are Ammon's horn, Purkinje cells, ependyma and blood vessels.

Conclusion.—The brain of animals killed directly in nitrogen is almost normal aside from subpial hemorrhages.

In contrast to the animals of group 1, in which the animals were permitted a short survival period, the circulatory and degenerative changes observed in group 2 are relatively slight. The actual damage to cerebral tissue in animals killed by anoxia should certainly be greater than in those subjected to sublethal anoxia, but it appears that a survival period is necessary for the change to become histopathologically apparent.

GROUP 3.—*Animals killed in nitrogen following repeated sublethal exposures at different days.*

One guinea pig (2) was killed in nitrogen after nine periods of anoxia, another (6) after twelve periods.

These animals showed a great number of subpial hemorrhages over the convexity and base of the brain. The pia was slightly thickened and contained an increased number of fibroblasts. The type of nerve cell changes was the same as in group 1 but the degree of the disease was more severe. The nerve cells of the deep cortical layers of Ammon's horn and the subiculum were pale, their nuclei shrunken and pyknotic, the cytoplasm of foamy appearance. Foci of blanching were present in the cortex, possibly in connection with fibrosis of the small arteries. In larger arteries the media was rich in fibroblasts and incrustated with a granular material giving the reactions of calcium.

Conclusion.—With repeated periods of anoxia the nerve cells become more severely damaged, and some cells disappear completely. The meninges and blood vessel walls show signs of fibrosis and incrustation.

In this group of animals the additional picture of the permanent damage following repeated anoxic exposures was seen. Apparently some of the changes seen in the animals in group 1 were irreversible, and these irreversible changes sum up to provide the pictures of extensive and permanent damage when the animals are repeatedly subjected to anoxia.

GROUP 4.—*Animals dying hours after nitrogen immersion.*

Animals dying spontaneously from eight to forty-eight hours after one or repeated immersions into nitrogen (12, ten hours after one immersion; 3, eight hours after twelve immersions; 5, forty-eight hours after twenty-four immersions at different days).

Fig. 6.—Section of fascia dentata of Ammon's horn of the animal that died forty-eight hours after the last of twenty-four exposures to nitrogen, showing ischemic cell necrosis. (Cresyl violet stain; reduced from a photomicrograph with a magnification of 550 diameters.)

The cortex of these animals was markedly damaged. The nerve cells showed a small pyknotic nucleus retracted from the cytoplasm, of which only a marginal zone was stained with basic dyestuffs. The cortex seemed to be devoid of ganglion cells (fig. 4). However, here again silver and hematoxylin stained sections indicated that more nerve cells were present than were visible in the cresyl violet stained preparations.

This is a condition well known, for instance, from the encephalopathy following whooping cough and has to be considered, as already mentioned, as a chemical rather than a structural damage.

The nerve cell changes were most pronounced in the granular layers of the cortex, while both the Ammon's horn (fig. 6) and the Purkinje cells showed the typical picture of advanced ischemic disease. There was a mild proliferation of the ependymal cells and in one animal (12) a localized, mild meningitis with lymphocytic infiltration.

In one animal of this group the nerve cells of the basal ganglia and brain stem were involved in contrast to all other animals of this investigation.

Conclusion.—The animals of this group, although exposed for about the same period of time to nitrogen as those of group 3, were microscopically more severely damaged. This could be suspected from the fact that these animals died spontaneously. More cells were structurally and permanently damaged than in the former group, as exemplified by the almost necrotic condition of the Ammon's horn cells.

This group of animals represents a peculiar situation in which the animals are able to survive immediate periods of anoxia but die hours later. These animals were studied by a thorough general autopsy, and no significant extraneural lesions were found. While this situation generally occurred following the last of several periods of anoxia, one animal had only one exposure.

GROUP 5.—Animals decapitated after repeated anoxia.

Animals decapitated after seven and twenty-nine anoxic periods, respectively (cat 8 and guinea pig 4).

The changes in the cortex of these animals corresponded closely to those of group 4, indicating that the form of death has no influence on the type or degree of cell disease. In this group the granular layers were again greatly involved, in some convolutions more the outer, in others more the inner granular layer. While the cell degeneration was laminar in the guinea pig, it was patchy in the cat. This cat was the only animal that showed at least a suggestion of glial reaction.

The degree of nerve cell damage in the guinea pig which underwent twenty-nine periods of anoxia does not correspond to the frequency of anoxia. As far as can be concluded from the small number of animals, increased nerve cell damage runs parallel to the increased frequency of anoxic periods up to a certain point beyond which cell loss does not progress further. The Purkinje and Ammon's horn cells were ischemic approximately to the same degree as in group 4. The meninges and blood vessels showed mild fibrosis. The number of subpial and perivascular hemorrhages was not markedly increased, compared with those found in group 4.

Conclusion.—Decapitation after repeated periods of anoxia gives essentially the same picture as that seen in animals which die spontaneously after repeated periods of anoxia. The cell damage is laminar in the guinea pig and patchy in the cat. The cat is the only animal showing a suggestion of glia reaction, whereas the glia in all other animals seems to be damaged, together with the nerve cells. Cortical cell damage seems to progress with increased frequency of anoxia only to a certain point and then to lag.

COMMENT

Anoxia acts on ectodermal and mesodermal tissue alike in the brain of the guinea pig and of the cat. This action becomes visible first after immersion of the animal in nitrogen for one-half minute and is more marked after one minute. These initial changes are mainly of metabolic nature, the cell chemistry being so altered that the cytoplasm becomes unable to take basic stains such as cresyl violet. It is likely that most of these changes are reversible. This is not so with the perivascular hemorrhages and coagulations, which necessarily destroy minute portions of brain tissue. Hemorrhages indicate, in addition, a lesion of the wall of the blood vessel as demonstrated by its increasing fibrosis and incrustation. Hence a secondary noxious

factor appears after several periods of anoxia, namely the decreasing permeability of the wall of the blood vessel.

Integration of these two factors leads, after a greater number of anoxic insults, to structural and apparently permanent lesions in the cortical cells. The distribution of the cell lesions is irregular, in some animals more laminar and more pronounced in the granular layers, in others patchy and more marked in the pyramidal layers.

In all animals but one the glia appeared to participate in the suffocation and did not show any sign of proliferation.

The impression prevails that with increasing frequency of anoxia the alteration in the central nervous system rapidly reaches a maximum which seems not to be surpassed even in animals so severely hit that they die spontaneously some time after the last immersion.

It must be taken into consideration that the histologic picture conveys but a vague idea of the function of a cell. Even the complete disappearance of a number of cells gives no indication as to whether the available reserve of nerve cells is still able to maintain normal function or as to when they too will be exhausted. Be this as it may, one point stands out, and that is that metabolic changes are very early demonstrable in brain cells of anoxic animals and that with repeated attacks of severe anoxia more and more nerve cells perish.

In the majority of the animals here presented there is much evidence to suggest that repeated and short periods of anoxia may produce a summated picture of considerable permanent damage to the brain. However, the experimental procedure used (complete anoxia) would rarely be encountered in man, either in aviation, industrial or laboratory activities. Yet it would seem reasonable to believe that these degenerative and vascular changes may also occur when anoxia is only partial. Van der Molen¹⁹ states that at oxygen partial pressures slightly less than half that at sea level, and equivalent to that at an altitude of about 28,000 feet, cortical cell changes occur. Presumably, some of these changes may become permanent and the result of repeated exposures of this type may decrease the ability of the brain to operate efficiently and compensate adequately for the destroyed tissue. An interesting fact in this connection is the common observation among aviators, stressed by Armstrong,²⁰ that, as their air experience becomes longer, their ability to fly at high altitudes becomes less. Whether this is a function of increasing age or is due to repeated exposures to low oxygen environments is not clear.

The negative result of repeated sublethal experimental exposures of guinea pigs and cats to anoxia, as far as function is concerned, is in accordance with experience in man. This does not mean that there are no functional disturbances but that our present methods of examining men and animals are not appropriate to demonstrate their presence. In fact, it is likely that the application of modern sensitive neurophysiologic and psychologic methods would show deviations from the normal.

Yet the present experiments indicate that exposure to anoxia of increasing duration or repetition is followed by graded severity of damage to the nerve cells in brain and brain stem. Even one single period of

19. van der Molen, H. R.: Question of Sequels of Narcosis or of Asphyxia: Experimental Studies on Effect of Oxygen Withdrawal on Central Nervous System, *Nederl. tijdschr. v. geneesk.* 83: 4921 (Oct. 14) 1939.

20. Armstrong, H. G.: Anoxia in Aviation, *J. Aviation Med.* 9: 81 (June) 1938.

anoxia of sixty seconds' duration leaves distinct traces of morphologic changes behind. There is no way of stating whether these damaged cells can recover. But the gradual increase of permanently damaged nerve cells and changes in the blood vessel walls, as well as in the meninges, points to the likelihood that no prolonged periods of significant oxygen lack leave the brain totally unscathed. The great reserve of nerve cells in the brain is probably responsible for the fact that functional compensation is possible for a certain time. However, this consideration should not allow one to overlook the organic sequelae of repeated though individually short lasting periods of anoxia, which, when summed up, may eventually lead to mental conditions comparable to those of the "punch-drunk" boxer.

SUMMARY

Exposures to sublethal periods of pure anoxia lead to vascular and degenerative changes in the brains of guinea pigs and cats. Some of these changes are irreversible and become summated in animals repeatedly subjected to anoxia. Because of quantitative differences in the extent of anoxia and the differences in species, these experiments cannot be translated directly to situations of oxygen deficit in man. Yet as demonstrating a general process these experimental results point to the possibility of a gradual lowering of the cerebral reserve in individuals repeatedly exposed to low oxygen environments.

THE EFFECT OF ALCOHOL ON
DRIVING SKILL

HENRY NEWMAN, M.D.
AND
EDWIN FLETCHER
SAN FRANCISCO

One important step toward the solution of the problem of drunken driving lies in the accurate diagnosis of drunkenness. That a definite correlation between blood alcohol concentration and intoxication exists in any large series of cases has been repeatedly shown, and on the basis of data so obtained rigid limits of blood alcohol concentration above which legal intoxication is assumed to exist have been fixed by several states. These all agree more or less with the figure pronounced by the National Safety Council of 150 mg. per hundred cubic centimeters of blood.

The experimental data on which this pronouncement has been made leave something to be desired from the standpoint of control and objectivity. As a matter of fact the point most frequently lost sight of is that, while the correlation may be excellent from the statistical standpoint, in order that a man may be convicted of drunken driving because his blood alcohol concentration was found to be 150 mg. per hundred cubic centimeters it is essential that this blood alcohol concentration be shown to produce legal intoxication not in a majority of individuals but in every individual. Failing this, it is inevitable that certain convictions will be unfairly obtained. With this in mind it is of interest to inspect the data which have appeared in the medical literature.

Bogen¹ found a high degree of correlation between the breath and urine alcohol concentration of patients

and their degree of intoxication as judged clinically. With alcohol concentrations below 100 mg. per hundred cubic centimeters none were adjudged intoxicated, with 100 to 200 mg. 50 per cent were intoxicated, with 200 to 300 mg. 75 per cent were intoxicated and with 400 mg. and over "almost" all were intoxicated. From this he concluded that tissue alcohol concentration was the best single criterion of drunkenness. Yet the variation in tolerance to alcohol is apparent from his own figures, which show that at alcohol concentrations of from 100 to 200 mg. per hundred cubic centimeters half the individuals were intoxicated, while some few were not so diagnosed with over twice this concentration, and if we were to subscribe to the limit of 150 mg. per hundred cubic centimeters laid down by the National Safety Council at least 25 per cent of the patients would have been wrongly convicted of drunkenness on the basis of alcohol concentration.

Similar results were reported by Jetter² in 1,000 hospital entries. Considering only the extremes, he found 10 per cent intoxicated at a blood alcohol level of 50 mg. per hundred cubic centimeters and 93.3 per cent at 400 mg. per hundred cubic centimeters. Thus an occasional individual was not considered intoxicated at a blood alcohol concentration eight times as high as that at which 10 per cent were considered intoxicated. Smith and Stewart³ are more conservative, considering the test of value in determining how much alcohol has been ingested but not in the diagnosis of the degree of intoxication.

This variation in tolerance to alcohol, which has long been a matter of common knowledge, was demonstrated experimentally in dogs by Newman and Card⁴ and in man by Bahnsen and Vedel-Petersen⁵ and by Schmidt.⁶ The latter administered a dose of alcohol to a group of subjects and determined its effect on various acts requiring the same type of skill required in motor driving. Individual variation was well demonstrated, for, though the majority showed significant losses in performance, some subjects showed an increase in skill, possibly attributable to practice.

EXPERIMENTAL WORK

It seemed desirable that the test situation should conform as nearly as possible to that prevailing in the actual operation of a motor car. The subject sat in an ordinary adjustable driver's seat. In front of him, in the normal position, were the steering wheel, clutch, brake and accelerator pedals. Behind the steering wheel an aperture at approximately eye level represented the outlook through the windshield, and in this aperture appeared a facsimile of the radiator cap and hood of a car, the movement of which from side to side could be controlled by the steering wheel. Behind the radiator cap, filling the aperture, was a photographic scene depicting a three lane highway, in the right hand lane of which the rear elevation of a truck was apparent. This scene was actuated by an irregular cam so as to move with varying speed in an unpredictable manner from side to side behind the aperture, and it was the

objective of the subject so to move the steering wheel controlling the radiator cap that this object remained directly in line behind the truck. An electric stop-watch recording hundredths of a minute remained in motion as long as the alinement of radiator cap and truck was maintained, but as soon as a deviation of one-eighth inch either way occurred the clock stopped and a signal light in view of the subject on the side to which the

Chart 1.—Distribution curve showing the concentration of alcohol in the blood after ingestion of a dose of 1 cc. per kilogram of body weight in seventy-nine trials.

deviation occurred went on. On correction of the deviation the light went out and the clock restarted. Thus the percentage of time that alinement was accurate could be recorded. This test will be referred to as simple steering.

In the road scene, close beside the truck, were two small holes, behind one of which was a green light and behind the other a red light. Pressing on the accelerator pedal caused the green light to come on. At an unpredictable time thereafter the green light would go out and simultaneously a red light would appear and a stop-watch recording hundredths of a second would start. It was the object of the test to press on the brake pedal as soon as the red light was perceived, causing it to be extinguished and the clock to stop, recording the reaction time in hundredths of a second. This test will be called simple braking. The two tests could be operated simultaneously, and this procedure was designated vigilance steering and braking. All the figures reported represent the percentage loss in efficiency after alcohol, referred to the control score of the same individual before drinking. Thus for each individual we had a test primarily of coordination, simple steering, one primarily of reaction time, simple braking, and one combining the two factors and bringing in more strikingly the factor of attention, vigilance steering and braking.

Alcohol was administered in the form of commercial whisky, diluted to taste with carbonated water and imbibed in fifteen minutes. The routine of the test was as follows: A minimum practice period of fifteen minutes, preferably on a day prior to the actual test, was required. This was effective in minimizing the possibility of increase in efficiency due to practice. When the subject presented himself at the laboratory for the test he was given five trials of simple braking, followed by one trial of simple steering, then three trials of vigilance steering and braking, then five final trials of simple braking, one of simple steering and one of vigilance steering and braking. The values reported are averages of all trials. Immediately on the completion of this control series, which required about fifteen minutes, the alcohol was given, and at the end of one hour

a second identical series of tests was given and a sample of venous blood taken for alcohol analysis.⁷

Ninety-eight such trials were performed on sixty-five subjects, of whom eight were women. The subjects, all in good health, consisted mainly of physicians and medical students, with a few skilled workers, and was thus fairly homogeneous as to general cultural level.

The dose of alcohol was 0.5 cc. per kilogram on four occasions and 1 cc. on seventy-nine, while in ten subjects an additional 0.5 cc. was given after the completion of the first test, and in one subject still an additional 0.5 cc. after the second dose, making 2 cc. per kilogram in all. The distribution of alcohol concentrations after the 1 cc. dose is shown in chart 1.

Considering the whole mass of data, the correlation between various factors was calculated by the Pearson correlation coefficient formula, with which a correlation coefficient of 1.0 indicates perfect and 0.0 no correlation. Comparing blood alcohol concentration in our series with percentage loss in vigilance steering and braking, which was undoubtedly our best measure of loss in driving skill, we obtained a correlation coefficient of 0.485 plus or minus 0.077. When it is recalled that a slightly better correlation, namely 0.5, exists between the height and weight of a population, it readily will be seen that the correlation between loss of driving skill as measured by our tests and blood alcohol concentration is not very great, as is graphically represented in chart 2.

The crude scores in the tests showed less correlation with loss in efficiency than the percentage loss in the tests, the variation in skill from individual to individual often outweighing the changes brought about by alcohol. When distribution curves for simple steering and simple braking before and after alcohol are constructed, it is apparent that, while there is a definite shift in performance toward the poorer side in both cases, considerable overlap of the curves is present. However, it is of interest to note that in spite of this the crude scores of simple steering show a correlation with our best index of intoxication, loss in vigilance steering and braking, of 0.576 plus or minus 0.068, which is actually

Chart 2.—Plot of percentage loss in efficiency in vigilance braking and steering against blood alcohol concentration for the entire group.

better than the correlation between loss of performance on the combined test and blood alcohol concentration. Thus it can be stated that performance in the test of simple steering is a better criterion of intoxication than is blood alcohol concentration and might be used profitably along with other tests in the diagnosis of drunkenness.

7. Newman, H. W.: The Determination of Ethyl Alcohol in Body Fluids, *J. Pharmacol. & Exper. Therap.* 56: 278 (March) 1936

An endeavor was made to break down the group as a whole into smaller groups of differing characteristics to determine possible variations from the general trend on this basis. No significant correlation was found between loss of efficiency from alcohol and the factors of age, sex, driving experience or drinking habits. With regard to the last of these, it should be noted that there were no really heavy drinkers in our series.

Several of the subjects made the statement prior to the test that in their opinion their driving skill was somewhat improved by moderate doses of alcohol, and a few felt that they did better in the test after drinking. It is of interest to note, therefore, that in no case was the performance in all the tests improved after alcohol. True, in seventeen of the trials there was improvement in one or more of the tests, but it is very probable that all these gains may be ascribed directly to practice rather than to any stimulating effect of alcohol, the gains being of the magnitude of those apparent in the control series.

COMMENT

The tests showed themselves to be well adapted to the demonstration of loss of efficiency in certain skills employed in the operation of a motor vehicle, giving consistent results in the same individual on different occasions. It was obvious that blood alcohol concentration in the individual case was a poor indicator of drunkenness as manifested by loss in skill in the acts tested, a fact in accord with the results of the previously published work cited. The important matter is to give full significance to this fact and not to carry over the apparent tendency for individuals with the highest blood alcohol concentrations to exhibit the greatest loss of skill into the arbitrary setting up of a fixed blood alcohol concentration at which a majority of individuals are intoxicated to apply equally to all individuals. If any blood alcohol concentration is to be accepted as absolute evidence of intoxication in the legal sense, it is essential that it be one at which experience has shown that no individual, regardless of his inherent or acquired tolerance, would be clinically adjudged sober. Concentrations lower than this might be of definite value as contributory evidence of drunkenness, but no more.

There can be little doubt that the operation of motor vehicles would be safer if the drivers were prohibited from consuming any alcohol whatever. However, the recent experiment with more generalized prohibition has effectively demonstrated the inability to enforce legislation so generally unpopular, whatever may be our opinion of the advisability of such laws. Public sentiment is definitely against the drunken driver but not against the drinking driver. Thus any attempt to control the problem by obtaining convictions on the sole basis of blood alcohol concentrations such as the 150 mg. per hundred cubic centimeters advocated by the National Safety Council must fail for the reason that such action would constitute the punishment of drinking rather than of drunken driving. Haggard,⁸ in defense of such measures, cites the speed limits imposed by most states as an example of legislation requiring all drivers to conform to standards safe for the least skillful of them. We are all familiar with the disregard for such laws shown by otherwise law-abiding citizens, so that rather than being an argument in favor of further legislation of the same type our experience

with arbitrary speed limits should point a lesson as to the public reception of similar laws in the future.

Rather should we look to the education of the operators of motor vehicles regarding the effect of alcohol on their driving abilities. For this purpose it is necessary that we amass data which will show that alcohol, even in moderation, does have a deleterious effect on the driving skill of most persons.

In spite of efforts at education, enforcement must always be a part of the campaign against drunken driving. For this to be justly and effectively carried out, two issues need to be clarified. The first of these is an adequate and uniform definition of intoxication as applied to drivers. The second is the development of tests which will establish the presence of this degree of intoxication. A rational procedure would seem to be the setting up of minimum standards of skill, as tested by as many procedures as possible, to be required of any person before he is allowed to drive a motor vehicle. A driver suspected of intoxication could then be retested, and if his performance fell below the accepted standard, and presence of alcohol in his blood was proved, a conviction should result regardless of the actual blood alcohol concentration found. Thus any person who so lowered his driving efficiency below the minimum accepted standard would be convicted, without penalizing other individuals of greater skill whose only offense consisted of the presence of alcohol in their blood stream.

BIOLOGIC FALSE POSITIVE SEROLOGIC TESTS FOR SYPHILIS

III. A SUGGESTED METHOD OF APPROACH TO THEIR CLINICAL STUDY

JOSEPH EARLE MOORE, M.D.

HARRY EAGLE, M.D.

AND

CHARLES F. MOHR, M.D.

BALTIMORE

Earlier papers of this series have drawn attention to the occurrence of biologic false positive serologic reactions for syphilis in normal persons¹ and in those with diseases or conditions other than syphilis.² For normal persons it has been estimated,³ on the basis of serologic surveys of large groups of presumably normal white American university students of both sexes, that the incidence of biologic false positive reactions in this particular population group is probably less than 1 in 4,000. As to diseases and conditions which may produce biologic false positive reactions, it has been further pointed out that their probable frequency is known, on the basis of published studies, only in yaws (100 per cent), leprosy (from 40 to 80 per cent), malaria (100 per cent at some time during the infection) and infectious mononucleosis (about 20 per cent). In diseases or conditions other than these no estimates of frequency are as yet possible, since the biologic false positive reaction in patients with acute infections is often only a transitory phenomenon, recognition of which may

depend not on single tests performed at random but on repeated tests, daily if possible, carried out during the entire course of the infection. Nevertheless, though estimates of incidence cannot be made, characteristic examples of biologic false positive tests have been reported² from our own clinic in acute infections of undetermined origin, acute infections of the upper respiratory tract (including pneumonia), vaccinia, infectious mononucleosis, rat bite fever and perhaps typhus fever. Within two or three years at least forty examples of biologic false positive tests, either in normal persons or in those with the diseases enumerated, have come under our personal observation, and twenty-one of these have been reported in the two papers already referred to.⁴

The recognition of such biologic false positive tests is of great importance, in view of the increasingly widespread use of routine serologic testing in medical practice, in industry and by legislative fiat (as in compulsory premarital and antepartum examinations). It is as thoroughly undesirable to make a diagnosis of and treat for syphilis a patient who does not have it as to miss the diagnosis in one in whom it exists. Every physician is familiar with the social and psychologic tragedies which may be precipitated by the diagnosis of syphilis, and every effort should be made to avoid false diagnoses.

Our concern in this respect, which has gradually increased during the past few years, is shared by others, notably Kahn,⁵ whose work on the subject will be mentioned presently.

In April 1940 one of us⁶ published a brief outline of a procedure for the attempted differentiation of biologic false positive serologic reactions for syphilis from those positive reactions actually due to the disease. It seems desirable, in view of the increasing importance of the subject, to amplify and expand this outline.

At the outset, it should of course be said that when a positive serologic reaction for syphilis is obtained in a patient who gives no history or shows no physical evidence of the disease the test should at once be repeated—and before the patient is told of the original result—in order to exclude a technical false positive result. This having been done, it is usually necessary to recheck both history and physical examination for actual clinical evidences of syphilis, since, unless the examiner has the possibility of syphilis in mind before the serologic reaction is first obtained, both are likely to be sketchily inadequate.

THE HISTORY OF SYPHILIS

It is common experience that a history of infection with syphilis is hard to obtain. Of patients with proved late syphilis of various types, at least one third of the men and one half of the women can give no story of early symptoms. As Stokes⁷ so well points out, this may mean that actually there were no early lesions, that the patient misinterpreted and dismissed as of no importance those which did occur or that he has really forgotten them. It may mean that the questions were asked in unfamiliar language rather than in the vernacular which the patient understands, that he was not questioned privately, that he was questioned in such a

manner as to imply that infection is inconceivable, or that a third degree tone was used. "No patient will admit ignominy, expressed or implied." Finally, it may mean that the patient was not asked about antisyphilitic treatment. A recent case comes to mind in which a careful examiner wrote on the patient's record "Denies syphilis by name and symptom" and was surprised to receive an unexpectedly positive serologic report and chagrined when a syphilologic consultant subsequently elicited from the patient (who had not intended to lie) a story not only of early syphilis but of three years' treatment for it, including seventy-two injections of an arsphenamine and sixty-one of bismuth, and two lumbar punctures!

When a history of infection with syphilis or of treatment for it is not obtainable, the risk of possible exposure should be asked for and noted. What story of premarital and extramarital sexual exposures can be elicited, and, if these occurred, were they infrequent and with social equals or promiscuous and with prostitutes? Is the patient married? If so, at least one contact can and usually must be examined for objective evidences of infection. Has the patient been married more than once? Such information as may be available concerning the former spouse's health and extramarital sexual habits should be obtained and, if dead, the cause of death. Has there been opportunity for extragenital infection, as in promiscuous kissing or, in the case of physicians, nurses and dentists, through professional exposure to syphilitic patients? Has the patient ever been infected with any venereal disease, especially gonorrhea? All these points are of collateral value in establishing the opportunity for infection with syphilis, if not its actual occurrence.

THE PHYSICAL EXAMINATION FOR SYPHILIS

A physical examination for syphilis is not complete unless it consists of thorough dermatologic examination (the patient stripped and the skin and mucosae carefully examined in good light), and thorough general medical and neurologic examination, including the use of the ophthalmoscope. The statement "There is no physical evidence of syphilis" is not acceptable unless at least this much has been done. When physical abnormalities are present, great care is sometimes necessary in their interpretation, as illustrated by two of our recent patients. One with herpes progenitalis and coincident pityriasis rosea had been elsewhere diagnosed as having primary and secondary syphilis; the other, with a retrosternal thyroid and perforation of the nasal septum due to chrome poisoning, had been thought to have syphilitic aortitis and a nasal gumma.

What serologic evidence of syphilis shall be accepted in apparently normal persons with no history of infection or of treatment for it? By and large, repeatedly positive serologic tests in a reliable laboratory, if confirmed by more than one standard technic (and especially if both a complement fixation and a flocculation procedure are used) mean latent syphilis in a person lacking history or physical evidence of the disease, provided there has been an opportunity for such infection to occur. Sometimes, perhaps often, it may be desirable to check the reliability of the laboratory by duplicate tests and by tests made in a different laboratory. Not only does this guard further against technical error but also a rare patient may, for unknown reasons, give consistently positive reactions in one laboratory and negative reactions in all others (Stokes has seen one such case, and one of us (J. E. M.) has seen another).

Quantitative serologic testing as a method of determining the validity of the serologic diagnosis of syphilis will be discussed in detail presently.

When shall serologic evidence of syphilis be doubted? As Stokes humorously puts it, there are "instances . . . in which one [positive] Wassermann test will convict a laborer over his own denial, two will make a case against a banker or a railroad president, but three successive positives will scarcely convince the medical adviser of the 'guilt' of a clergyman." True as this is, every physician has patients for whom, for entirely personal and mostly undefinable and intangible reasons, he is hesitant to accept a purely serologic diagnosis of syphilis.

Specifically, on clinical grounds, he is justified in suspecting as false a positive serologic result in at least two categories of patients: (1) young girls or young women who, lacking history or physical evidence of syphilis, have not been demonstrably sexually exposed (virginity should be objectively demonstrated in such cases by intactness of the hymen), and (2) persons of either sex and of any age who, also lacking historical or physical evidence of syphilis, are found to have positive reactions at an interval after one or more previously negative reactions and who deny exposure in the interim (examples of each of these categories are cited in one of the previous papers of this series¹).

On serologic grounds, one is justified in suspecting as false a positive reaction in a patient who, lacking historical or clinical evidence of infection and, whatever his history of potential exposure, gives a series of conflicting results when tested by different technics or at different laboratories.

SUGGESTED PROCEDURES WHEN BIOLOGIC FALSE POSITIVE TESTS ARE SUSPECTED

The diagnosis of syphilis is so potentially serious that whenever the suspicion of it arises every effort should be made to verify or deny it. When there is clinical or serologic reason to doubt a confirmed positive serologic report, a number of procedures, some clinical, some laboratory, should be instituted as aids in arriving at a conclusion. None of these procedures, taken alone, are definitive; the ensemble is usually necessary. The first has already been mentioned, i. e. an exhaustive anamnestic and physical search for evidences of syphilis itself. If, as is often the case, such a search is fruitless, one should proceed as follows:

1. Take a careful history as to (a) symptoms of some intercurrent infection of whatever nature, (b) serum treatment (including tetanus antitoxin) or (c) vaccination within the four months preceding the questionable serologic test. It must not be forgotten, as some of our illustrative cases show,² that a reagin-like substance may persist in the blood for several weeks or even months after recovery from certain acute infections.
2. Make a careful physical examination for evidences of acute infection preceding the questionable serologic test, with special reference to lymph nodes, spleen and lungs. The lymph node enlargement of infectious mononucleosis may persist for several weeks after the acute infection subsides, as may also basilar remains of an acute infection of the upper respiratory tract.
3. Make a thorough search of blood smears for malarial parasites. This is especially important in the Southern states, where malaria is endemic and chronic malarial carriers are common.
4. Examine blood smears for infectious mononucleosis. This may involve inspection of the smear and a

differential count by a trained hematologist. Abnormal cells of the lymphocytic series are especially important. The cytologic abnormalities of infectious mononucleosis tend to disappear promptly with subsidence of symptoms of acute illness (Bernstein³), and the smear may be normal at a time when the false positive serologic test persists.

5. Make a blood test for heterophile antibody (the Paul-Bunnell test). This is specific for infectious mononucleosis. Heterophile antibody tends to persist in the blood for from four to five months after the onset of acute symptoms of illness and gradually to disappear. It has been reported to persist for as long as six months (Bernstein). The disappearance of the positive serologic test for syphilis does not necessarily parallel the disappearance of heterophile antibody; the duration of the former is usually brief, but it may persist for as long as three months after recovery from illness.

In connection with paragraphs 4 and 5, it should be emphasized that infectious mononucleosis is almost certainly a much more common infection than it is usually thought to be. Its apparent prevalence among physicians, nurses, medical students and hospital employees is due only to the fact that such persons, being constantly in or near hospitals, are much more likely to have blood counts made for minor acute infections than are other patients. Further, it should be emphasized that the clinical manifestations of the disease are often trivial, consisting of no more than a day or two of slight sore throat with low grade and perhaps unnoted fever. Infectious mononucleosis is a possibility seriously to be investigated in all suspected false positive serologic reactions, especially in young persons.

6. Determine the sedimentation rate. The sedimentation rate is thought to be considerably increased in early syphilis and in neurosyphilis; it may be normal or, more frequently, slightly increased in late and in latent syphilis. Also it is frequently increased to an even greater degree in many of the acute infections, which may be responsible for false positive serologic reactions. In the latter, it tends to fall toward normal as the acute infection subsides; in syphilis, on the contrary, it tends to remain moderately elevated until some weeks after the institution of antisyphilitic treatment. A greatly increased sedimentation rate observed during an acute illness, which is accompanied by positive serologic tests for syphilis but which tends spontaneously to fall toward normal as acute symptoms subside, speaks moderately in favor of a biologic false positive serologic reaction. On the other hand, normal sedimentation rates may occur in normal persons with biologic false positive serologic reactions.

7. Repeat serologic tests for syphilis by several different technics including both complement fixation and flocculation, at least one of which is quantitatively titrated.

This requirement leads to a brief consideration of the value of serologic quantitation in the diagnosis of syphilis, a subject which has been considered in detail in another paper of this general series.⁴ In general, enormous variations in titer (from 0 to 1,600 units) are observed in all types of clinical involvement, including both early and late syphilis. On the average, the reagin titer is higher in early syphilis (100 + units) than in

8. Bernstein, Alan: False-Positive Wassermann Reactions in Infectious Mononucleosis, *J. M. S.* **196**:79 (July) 1938; *Infectious Mononucleosis*, *J. M. S.* **197**:85 (Feb.) 1940.
Eagle, Harry: The Value of Quantitative Serologic Tests, to be published.

any form of late syphilis (from 20 to 50 units). A single quantitative titration by any technic is therefore of no diagnostic value, since a low titer test is as likely to mean syphilis as a high titer test. In general, therefore, the only significance to be attached to a single titer test is in those patients, usually young, who, if infected with syphilis at all, have probably acquired the disease recently and who might therefore be expected to give high titer reactions.

Kahn¹⁰ has suggested that quantitative titration should be of value in differentiating false positive serologic tests from those positive tests actually due to syphilis, in that the former should be generally low and the latter generally high in titer. In our experience, the false positive serologic reactions occurring in normal persons¹ are usually low titer (from 0.5 to 5 units). Among persons suffering from diseases other than syphilis, far too little experience with serologic quantitation has accumulated to permit any conclusions as to titer in nonsyphilitic diseases, with the exception of leprosy, in which Wassermann titers are often high and flocculation titers usually low;¹¹ but enough information is contained in our own material² to indicate that even high titer reactions may be caused by still other nonsyphilitic conditions.

While a single quantitatively titered test is of no definitive value in differentiating false from true positive tests, a series of such tests over days, weeks or even months may be decisive. In general, if the positive reaction is false, it tends spontaneously to decrease in titer and finally to disappear. On the other hand, if the positive reaction is due to syphilis, it may, in the absence of antisyphilitic treatment, either spontaneously increase in titer (early syphilis) or remain at about the same level. In this connection it must be emphasized that serial quantitative titrations, to be of any value, must be carried out in the same laboratory by the same technic (preferably flocculation rather than complement fixation) and even then such tests are only roughly comparable, owing to unavoidable day to day variations in the sensitivity of the test.

As to serologic quantitation, then, the only value of a single test is that one may suspect as false low titer tests in young persons, who, if infected at all, may be presumed to have been recently infected and who should therefore have large amounts of serum-reagin.

The requirement that serologic tests be performed by several different technics necessitates another word of caution. Serologic tests vary in sensitivity both qualitatively and quantitatively. Qualitatively they may differ in the sense that in some cases a complement fixation test may be positive when more sensitive flocculation tests are negative. So far as our experience goes, such paradoxical results are largely confined to the following clinical categories:

(a) Patients with late congenital syphilis, treated or untreated¹² (the reason for this phenomenon in untreated late congenital syphilis is unknown).

(b) Patients with acquired syphilis who have had a great deal of antisyphilitic treatment.

(c) Infectious mononucleosis, malaria and perhaps other nonsyphilitic conditions.

Quantitatively, flocculation tests are in general more sensitive than complement fixation tests¹³ and may be divided into two groups: supersensitive screen procedures (Kahn presumptive, Kline exclusion) and less sensitive standard diagnostic procedures (Kahn, Kline, Hinton, Eagle). When several technics are used, the physician is justified in suspecting as false positive results which are paradoxically negative with more sensitive and positive with less sensitive technics.

8. Repeat serologic test for syphilis in several different laboratories of known excellence in order to rule out all possibility of technical error. Suspect as false tests positive in one laboratory, however, excellent, and negative in all others.

9. Perform the Kahn "verification test." This procedure, described by Kahn and his associates⁵ in several recent communications, depends on the fact that syphilitic reagin appears to flocculate the Kahn antigen best at 37 C., while the reagin-like substance present in the blood of many lower animals, of the occasional normal human being and of some patients with diseases other than syphilis flocculates best at 1 C.

In this connection it should be pointed out, however, that Kahn's work with this test is as yet on a small scale and has not been confirmed by other investigators. Until it rests on firmer ground than at present, a negative "verification test" should not be accepted as absolute evidence of the false positivity of other serologic tests.

10. Test the patient's serum by complement fixation with spirochetal antigen (the Reiter or Kazan strain of cultured *Spirochaeta pallida*). This test, known in Germany as Gaetgen's "palligen" test, has a considerable European literature. In this country Eagle has studied it,¹⁴ though unfortunately the antigen is not yet commercially available in the United States. There is reason to believe, however, that such spirochetal suspensions may give more specific results than tissue lipoids used in the Wassermann and flocculation tests, thus permitting the identification as false reactions of some of the positive results obtained in the absence of syphilitic infection. This is certainly the case in leprosy¹⁵ but is apparently not true in malaria.¹⁶ Other nonsyphilitic diseases have not yet been sufficiently studied to permit conclusions in this respect. Several of our apparently normal patients¹ as well as those with nonsyphilitic diseases² have, however shown negative results with a spirochetal complement fixation test while positive with standard technics, and we have laid some weight on this point in the final decision as to the validity of serologic results.

11. Test the patient's serum with wholly nonspecific antigens, such as those prepared from bacteria (the gonococcus, staphylococcus, tubercle bacillus) or from such substances as milk and lecithin. Certain persons apparently possess the peculiar property of reacting positively to all complement fixation tests. One such case has been reported by us (case 2).¹

12. Moore, J. E.: Proceedings Assembly of Laboratory Directors and Serologists, *Ven. Dis. Inform.*, supp. 9, 1939, p. 59.

12. Carry out a prolonged serologic follow-up (weeks or months) by a good quantitative technic, testing the blood at frequent intervals without instituting anti-syphilitic treatment. As already emphasized, these tests must be performed in the same laboratory by the same technic. False positive tests tend spontaneously to fall in titer; those due to syphilis tend to remain unchanged or to rise. The length of time that may be necessary to arrive at a decision is exemplified by the cases reported in our two previous papers.⁴

13. Examine members of the family and sexual contacts. This step in the examination may be extremely important. The suspicion of congenital syphilis, for example, may be dismissed if father, mother and siblings prove to be nonsyphilitic. The suspicion of acquired syphilis, especially if thought to be recent, may often be lessened if not dismissed entirely by the discovery that a husband or wife, constantly and intimately exposed and almost certain to have been infected were the patient syphilitic, has remained normal.

14. Examine the cerebrospinal fluid if a decision cannot be reached earlier. When there are genuine reasons for believing that the positive result is false, do not adopt spinal puncture as the first step in the investigation, since often a clearcut exploration (e. g. of infectious mononucleosis) can be found for the supposed false positive result. Unless the reason for false positivity is obvious, however, the patient should not be dismissed without a study of the spinal fluid, lest asymptomatic neurosyphilis be missed, with subsequent perhaps tragic results.

15. The so-called provocative procedure (injection of an arsphenamine with following quantitative serologic testing daily for fourteen days) is in our opinion worthless. In another paper of this series¹⁷ we have cast doubt on the existence of the provocative phenomenon.

16. Finally, withhold antisyphilitic treatment unless and until the diagnosis of syphilis is proved. Such treatment is dangerous and should not be given unless the risk is justified by the actual existence of syphilis.

SUMMARY

From an outline of a method of approach to the differentiation of the biologic false positive serologic reaction from the positive result due to the presence of syphilitic infection, it is obvious that many of the suggested procedures require special clinical or laboratory expertness and that the final decision as to the presence or absence of syphilis in a given case is a highly individualized problem which often requires weeks or months of observation and expert syphilologic advice.

A Much Abused Term.—The term "scientific" in these modern days has come to be much abused. Many things that are popularly looked on as being scientific, and many persons who are said to look on life from a scientific point of view, are no more scientific than an infant in its cradle, however much the child is in process of being brought up on so-called scientific principles with a pediatricist on one side scientifically to measure its vitamins and calories day by day and a psychologist on the other scientifically to protect it from complexes—perhaps even to provide an infant chimpanzee as a comparative playmate. Thus does the quasi-Science of Medicine sometimes lead to absurdities from which medical practice, largely controlled by common sense, usually escapes.—Cushing, Harvey: *The Medical Career and Other Papers*, Boston, Little Brown & Co., 1940.

HYPOTHERMIA

SUBNORMAL TEMPERATURE AND ITS RELATION TO NEUROCIRCULATORY ASTHENIA (SOLDIER'S HEART)

HOBART A. REIMANN, M.D.

PHILADELPHIA

Over a period of several years, persons without obvious infection or organic disease whose average temperature was slightly but continuously higher than the usually accepted normal were selected for special study.¹ Of twenty persons studied, seventeen were women. Most of them had been suspected for months or years of having some obscure underlying infection or other disease to account for the "fever" and many had been needlessly subjected to prolonged expensive investigation or treatment to discover the cause. Because of the elevated temperature the condition was at first regarded as habitual hyperthermia, but it soon became evident that in most cases the "fever" was only one factor among many others which occur in certain so-called neurotic persons. Furthermore, most of the neurotic patients had signs and symptoms of syndromes commonly known as sympathicotonia or vagotonia, chiefly the former, or a combination of the two. It was also pointed out that average body temperature may vary among different normal persons just as does the pulse rate or blood pressure, and deviations from the accepted standard of the norm need not always be looked on as evidence of disease. Nevertheless a person whose average oral temperature is higher or lower than 37 C. (98.6 F.) and has the symptoms of a neurosis of whatever nature can hardly be regarded as normal. The calculated probable incidence of persons whose temperature consistently deviates from 37 C. (98.6 F.) is illustrated in chart 1.

As a matter of further interest a search was then made for persons whose average temperature is subnormal and falls under the left leg of the curve. Over a period of three years, hospital charts were continuously scrutinized for samples of temperature tracings which were consistently below the normal level. Patients with myxedema, Addison's disease, cachexia or shock or convalescent from infections or with chronic conditions known to cause or to be accompanied by hypothermia were excluded.

It was remarkable that the nine patients with hypothermia eventually selected for study were all men with predominant symptoms and signs of vagotonia. It may be recalled that, in studies of hyperthermia previously referred to,¹ most of the patients were women.

As the studies progressed it became more and more evident that the patients selected for observation had most, if not all, of the signs and symptoms characteristic of "neurocirculatory asthenia," variously called "soldier's heart," the "irritable heart of soldiers," "disturbed action of the heart" and "effort syndrome."² Had these cases been encountered during war time most of them no doubt would have been classed as such. Since neurocirculatory asthenia is a serious problem in all great wars, it is bound to be of immediate importance in this country as soon as the draft of men

for military service begins. It causes many difficulties in diagnosis and is one of the most frequent causes of invalidism among soldiers.

REPORT OF CASES OF HYPOTHERMIA

CASE 1.—A. F., a Jewish house painter aged 50, first came to the hospital in March 1936 complaining of pain in the left lower quadrant, loss of weight and general weakness for a year. He had had heartburn and constipation for years. His tonsils and all his teeth had been removed without relief of his symptoms. On physical examination no important abnormalities were discovered. Evidence of slight hypertrophic osteoarthritis of the spine was found on roentgenography. Laboratory studies of the blood and urine, including search for the presence of lead because of possible lead poisoning, gave negative results. A diagnosis of osteo-arthritis of the spine and sacro-iliac joints was made at that time.

The patient returned to the hospital a year later again complaining of backache, upper abdominal pain especially at night, anorexia and weakness. Certain powders given by his own physician often relieved the abdominal pain. Constipation was severe. Physical examination again showed nothing of diagnostic importance. Chemical studies for lead poisoning gave negative results. The blood, urine, gastric juice and bile were normal. The basal metabolic rate on two occasions was minus 17 and minus 25. Because the heart rate noted on the chart varied between 40 and 60 beats per minute, heart block was suspected but an electrocardiogram showed no abnormalities except bradycardia. No attention was paid to the temperature, which usually varied between 36.1 C. (97 F.) and 36.6 C. (98 F.) and did not reach 37 C. (98.6 F.) at any time. The blood pressure varied between 84 and 100 systolic and 55 and 70 diastolic.

Because of the low basal metabolic rate, thyroid substance was given first in 0.06 Gm. (1 grain) doses three times a day, later in 0.12 Gm. amounts and finally 0.54 Gm. (9 grains) a day for a period of two weeks. He complained of increased nervousness and dizziness and the drug was stopped. The basal metabolic rate rose to plus 12 during this treatment but fell to plus 2 a week later. There was no change in the symptoms, temperature level, pulse rate or blood pressure.

The patient tried to return to work but could not because of weakness. His wife said that the patient complained of symptoms only when his mind was unoccupied.

I became interested in the patient's temperature at this time and requested his return to the hospital for special studies. He now complained of insomnia, exhaustion and palpitation of the heart. This time the temperature as plotted never rose over 36.6 C. (98 F.), the pulse rate varied between 42 and 65 and the blood pressure between 80 and 100 systolic and 48 and 70 diastolic. The hospital chart is reproduced in chart 2. The subcutaneous injection of histamine hydrochloride 0.75 mg., atropine sulfate 1 mg., pilocarpine hydrochloride 1 mg. and of powdered opium 0.12 mg. orally on different occasions did not produce the abnormal effects said to occur in cases of vagotonia or sympathicotonia. Dryness of the mouth occurred after giving atropine, and a transient slight increase in pulse rate and blood pressure occurred with pilocarpine. Pressure on the eyeballs for two minutes caused no striking changes in blood pressure or heart rate. Jumping exercises caused the pulse rate to rise from 40 to 100 per minute but it returned to 40 after three minutes of rest. Amphetamine sulfate 20 mg. seemed to increase the pulse rate on two occasions from about 50 to 80 and once the blood pressure rose from 85 systolic, 50 diastolic to 110 systolic, 70 diastolic for eight hours. Amphetamine sulfate, in fact, when given daily in 10 mg. doses was the only medication which made the patient feel more energetic and active.

The patient was regarded as having a form of neurosis. He could be classed as a vagotonic type, in Eppinger and Hess's scheme, as far as the bradycardia and hypotension are concerned, but for the presence of constipation and normal response to drugs which supposedly stimulate the parasympathetic system. The low basal metabolic rates suggested hypothyroidism but treatment with thyroid substance failed to influence any

of the signs or laboratory manifestations except the basal metabolic rate and caused mild symptoms of hyperthyroidism.

Because of the nature of the patient's complaints, his psychiatric reactions, the hypothermia, bradycardia and hypotension, he was regarded as a type of person in whom such phenomena are characteristic. They have often been classified as having vagotonia or neurocirculatory asthenia.

CASE 2.—H. N., a Jewish machine operator aged 54, complained of dizziness, attacks of vomiting, weakness and anorexia for six or eight months. Ten years before he had had all his teeth extracted for joint pains, and eight years before a peptic ulcer was diagnosed. He recovered without treatment. Two months before, according to a roentgenologist, he was said to have had colitis, but no symptoms were present.

Physical examination revealed essentially normal conditions except that chronic catarrhal otitis was present. His temperature during eighteen days of observation varied from 36 C. (96.8 F.) to 36.6 C. (98 F.) and rose to "normal," or 37 C. (98.6 F.), only twice. The pulse rate varied between 55 and 74, averaging about 65. The blood pressure was quite constant at 90 systolic and 60 diastolic. It reached 120 and 70 on one

Chart 1.—Curve of the probable incidence of average normal oral temperature constructed from a table prepared by Dr. Frances Vanant.

occasion. An electrocardiogram and laboratory studies of the blood, urine and gastric contents gave negative results. The basal metabolic rate was minus 19.

The patient reacted normally to the injection of pilocarpine hydrochloride, epinephrine hydrochloride, ergotamine tartrate and physostigmine.

The patient's symptoms disappeared without therapy and he left the hospital seemingly improved.

Although a diagnosis of neurosis may not be justified in this case since chronic otitis was found, his past history, present symptoms and relief without special therapy strongly suggest it. The low basal metabolic rate was not regarded as pathognomonic of hypothyroidism but, as in case 1, was presumably part of general constitutional habitus together with hypothermia, hypotension and bradycardia.

CASE 3.—S. Y., an unemployed Jew aged 60, complained of backache for fifteen years and nausea and pains in the shoulder since losing his job two years before. No important abnormalities were found on examination, except absence of all teeth. Laboratory and roentgenographic studies gave negative results except for an electrocardiogram in which the PR interval registered 0.24 second. The extreme range of his temperature over a fourteen day period of study was 35.2 C. (95.6 F.) and 37.3 C. (99.2 F.), the usual range from 35.5 C. (96 F.) to 36.6 C. (98 F.). It seldom exceeded 36.6 C. (98 F.).

The pulse rate was quite constant at 74 but the blood pressure was irregular, varying from 86 to 125 systolic and 56 to 80 diastolic.

The psychiatrist, Dr. Keyes, regarded this patient as having an "unemployment" neurosis.

CASE 4.—W. S., a physician's son aged 19, was known to have occasional albuminuria which gave a good deal of concern to his family. There were no complaints except frequency of urination when exposed to cold. He was tall, thin and pale and was of the "asthenic" type. No physical abnormalities were detected. Test of the urine showed no albuminuria while the patient was recumbent but from one plus to three plus while erect, particularly after exercise. There were many cylindroids and a few hyaline casts in most samples. The condition was regarded as orthostatic or postural albuminuria. His blood pressure while resting ranged from 108 to 130 systolic and 50 to 65 diastolic. It was not elevated by the moderate exercise of jumping twenty times but rose rapidly to 280 systolic and 110 diastolic after five minutes of rapid stair climbing.

Chart 2.—Hospital course in case 1. Hypothermia, hypotension, bradycardia and low basal metabolic rate are noteworthy.

The pressure returned promptly to its usual level on rest. The pulse rate at rest varied from 54 to 72 beats per minute but increased rapidly during exercise. The temperature never rose above 36.9 C. (98.4 F.) during three days of observation. During the day it averaged 36.6 C. (98 F.) and at night 36 C. (97 F.). The lowest level recorded was 35.6 C. (96 F.).

In this case albuminuria attracted the attention and the hypothermia, hypotension and bradycardia would perhaps have been disregarded on casual study. The patient was of the asthenic, visceroptotic type with a labile and unstable vasomotor system.

Five other cases were studied which were similar and need not be described in detail. The ages ranged from 21 to 44 years and three of the patients were born in Europe. In four, gastrointestinal complaints, including dryness of the mouth, were predominant for months or years, and in one there were numerous bizarre complaints of chills, dizziness, choking sensations, dry throat, palpitation of the heart, bitter taste, headache, weakness and constipation, symptoms which

are typical of a neurosis. Cold sweaty hands and dermatographia were present. One patient had the dilated pupils and the tachycardia characteristic of sympathicotonia yet his temperature was usually subnormal. Only one of the five showed an unusually strong reaction to small doses of atropine and of pilocarpine with marked dryness and hypersecretion respectively, although the pulse rate and blood pressure were unaffected. The temperature of all five patients averaged below normal, usually with bradycardia and hypotension while at rest. Exercise or emotional excitement often caused an exaggerated increase in the pulse rate and blood pressure. According to the psychiatrist, four of the patients had psychoneurosis. Their basal metabolic rates varied from minus 11 to plus 5.

COMMENT

In contrast to previous studies¹ of twenty cases of hyperthermia which were found to occur chiefly in women with evidence of sympathicotonia, all nine patients with hypothermia included in this report were men, most of whom were classed as vagotonic. While this predominance of one sex or the other in the two conditions seems suggestive, too few cases have been observed to judge whether such a difference is the rule or not. Information on consistent differences in temperature of men and women is meager. Recently Hardy and Millhorat,³ in experiments on three women, found that the skin temperature of women was higher than that of men but only in a warm atmosphere. In a study among normal children,⁴ girls were found to have temperatures over 99 F. more often than boys. Rautmann,⁵ on the other hand, found the average temperature of a group of normal women a fraction of a degree lower than that of men.

It seemed that, in most patients studied, those whose average temperature was above normal usually gave evidence of sympathicotonia¹ while those with hypothermia were usually vagotonic, yet it is of interest to note that a given patient seldom had all the signs of either one syndrome or the other and more often had a mixture of the two. For example, several of the men with hypothermia gave the usual evidence of vagotonia with bradycardia and hypotension but complained of dry mouth and constipation and had dilated pupils, which are characteristic of sympathicotonia. One of them had tachycardia. At any rate the patients all showed evidence of nervous instability or imbalance. Evidence of slight imbalance may be found perhaps in the majority of otherwise normal persons in civil or military life. It is only when it becomes severe enough to cause noticeable disturbances that medical aid is sought. In certain persons accidents, injuries, psychic shock, infections or the physical and emotional strain during war or threatened war bring the symptoms to a clinical level. A list of the more important characteristics of vagotonia and sympathicotonia is given in the accompanying table.

While the existence of either hypothermia or hyperthermia alone may seem unimportant, their recognition together with other evidence of nervous imbalance, as reflected in various systems of the body, may give a clue to a correct diagnosis in certain puzzling cases. Much needless surgery or other unnecessary investiga-

tion may thus be avoided and management guided along proper psychotherapeutic or physicaltherapeutic lines. As in most obscure diseases, undue attention has been given to foci of infection as a cause,² and many needless operations have been performed in the hope of relieving the symptoms. In this series of nine cases, the tonsils and some or all of the teeth had been removed in six, without beneficial effect. The symptoms in one case began immediately after tonsillectomy.

The majority of patients with hypothermia complained of gastrointestinal disturbances, various aches and pains throughout the body, dizziness, weakness and cardiac discomfort. Because of the variety of complaints, a variety of diagnoses was made in most cases, depending perhaps on the interest or specialty of the physician or succession of physicians consulted by the patient. For instance, in case 1, according to the opinion of different physicians, the occupation suggested lead poisoning, the complaints suggested arthritis and gastrointestinal disease; low blood pressure was considered as a cause of the disturbance, low basal metabolic rates suggested hypothyroidism, and bradycardia suggested heart block. Consequently numerous minor surgical operations, expensive laboratory investigation and many drugs were employed in diagnosis and treatment, most of which could probably have been avoided had less attention been focused on isolated signs and complaints and the syndrome recog-

Some Characteristics of Vagotonia and Sympathicotonia

Vagotonia	Sympathicotonia
"Wet" type with increased oral, nasal, bronchial, intestinal and other secretions	"Dry" type with decreased secretions
Low temperature	High temperature
Low basal metabolism	High basal metabolism
Low blood pressure	High blood pressure
Slow pulse rate	Fast pulse rate
Vasodilatation	Vasoconstriction
Increased peristalsis	Decreased peristalsis
Contracted pupil	Dilated pupil

nized as a whole. Patients of this type are commonly diagnosed as having colitis, chronic appendicitis and focal infection and are often turned into the class of the "much operated on" chronic invalid so well known to most practitioners.

Granting that the type of patient described here belongs to that group of persons who are subject to vasoneurotic disorders and come into especial prominence in wartime, it is questionable whether such names as "soldier's heart" or any other terms directing attention chiefly to the vascular system are desirable. The terms have come into current usage perhaps because of the more obvious symptoms and the ease with which the pulse rate can be counted, but it is certain that many other abnormalities can also be found if sought for. It is thought that all the signs and symptoms, as in the cases described in this paper, are evidence of a neuropathic disposition based on hereditary and constitutional inadequacy.²

SUMMARY

Nine patients were studied whose temperature level was consistently subnormal. Besides hypothermia they usually had other signs and symptoms of vagotonia such as hypotension, bradycardia, palpitation, sweating, low basal metabolic rates and numerous bizarre complaints for which no organic basis could be found. The symptoms and signs manifested by these men are the same as those described in the conditions known as neurocirculatory asthenia, effort syndrome or soldier's heart and probably arise from similar causes. Unless patients of this type are given a correct diagnosis they

may be subjected to much needless investigation and treatment and may be assigned to tasks beyond their limitations during military service. After possible organic causes for their disorder have been ruled out, treatment along psychotherapeutic and physical therapeutic lines is helpful.

EPIDEMIOLOGY OF TUBERCULOSIS

CÓRDOBA, ARGENTINA

In the long known nations, such as China, Egypt and Greece, consumption was described soon after man began to make permanent records. Where the disease originated we do not know, but its contagiousness was early suspected. As transportation developed, first through the use of beasts of burden and marching armies, then by sailboats, steamships, railroads, automobiles and finally airplanes, the disease was carried by persons in whom it was unsuspected and by persons who sought recovery of health from an ocean voyage or a change of climate.

For a long time there remained parts of the world where tuberculosis did not exist in man or animals. As it was carried to these places it spread among the natives, as it must have originally done in the long civilized countries. In some places it appeared in epidemic form, as manifested by illness of its victims. In all places it was in epidemic form but man did not have the refined methods of detecting its presence and it was therefore unsuspected in the majority of persons who had it and was recognized only in those whom it struck down. Not long ago the belief was held that tuberculosis was rare in the interior of Africa, but careful examination of 200,000 African boys employed in the gold mines revealed that 65 per cent had this disease in some phase of its development.

Of all the contagious diseases, tuberculosis has been the most difficult to control, partly because as it sweeps through a tribe, a family or a nation it does not leave a high percentage of immune persons, as does smallpox; on the contrary, it leaves the majority of those whom it attacks with living tubercle bacilli in their bodies, with serious future potentialities in many of them. It continues to strike these persons down, who if they had suffered from smallpox would be immune to that disease. The number of infected persons who fall ill each year is relatively small, but over a period of thirty or forty years the aggregate is large and is alarming to any nation that allows the disease to continue unmolested.

If tuberculosis is not opposed in a nation it will ultimately be present in some phase of its development in almost 100 per cent of the population. Among the animal herds, particularly cattle, if no control measures are used, it doubles itself every fifteen years.

Prepared with the aid of a grant from the medical research fund, University of Minnesota.

From the Departments of Preventive Medicine and Internal Medicine, University of Minnesota Medical School, and the Lymanhurst Health Center, Minneapolis.

Read in the Symposium on Pulmonary Tuberculosis before the Section on Practice of Medicine at the Ninety-First Annual Session of the American Medical Association, New York, June 12, 1940.

There was a time when it was thought that tubercularization of a nation of people was the only solution of the tuberculosis problem; that is, every one should be infected with tubercle bacilli. However, observation has revealed that in the nations where tubercularization is well nigh complete and where it has been in effect for centuries the morbidity and mortality from this disease are alarming. For example in China, where tuberculosis has existed for 5,000 years or more, one would expect a low incidence of clinical tuberculosis and a small death rate if tubercularization is the solution. In reality, in 1926-1927 Li reported that the mortality from tuberculosis in Peiping was 524 per hundred thousand and from 1927-1931 it was still 384, while from 1928 to 1932 in Shanghai the mortality rate was 244 and in Hong Kong 319. If these rates obtain throughout China with 400,000,000 or more people, approximately 1,200,000 lose their lives annually and if the Framingham, Mass., survey figures with reference to the number of living clinical cases per annual death are applied there now exist in China more than 10,000,000 persons with clinical tuberculosis, which Lee says is "a figure far exceeding the worst of any known epidemics in China."

In no nation where tuberculosis has been allowed to gain a foothold among the people or the domestic animals has it been known to die out; on the contrary, it spreads. Efforts of man have partially controlled it, as indicated by the reductions in morbidity, mortality and infection attack rates, but no nation has eradicated it. Witness the progress in controlling tuberculosis in some of the European nations before the World War and then observe how it spread like wildfire toward the end and immediately after the war in the same nations, largely because man's efforts against it were relaxed during the period of the war.

Another reason that tuberculosis has been so difficult to control is that it has always been so "kind to its hosts." The bacilli find lodgment in the tissues; they multiply and usually cause no unpleasantness until many of their progeny have been eliminated and have found habitations in the bodies of other persons. By the time the original host is aware of the presence of the disease through various symptoms, many of the patient's associates have already been infected and the lesion has made such inroads in the original case that an ultimate fatal issue is almost certain in a high percentage of persons. Therefore the healthiest appearing person in the community or the sleekest animal in the herd might be disseminating tubercle bacilli from lesions which had caused no incapacity.

The incubation period of tuberculosis ranges from three to seven weeks. At the end of this time mild symptoms may appear, such as elevation of temperature and slight malaise. There usually is no cough or expectoration, even when the lesions are located in the lung. The tissues are now found to be sensitized to the protein fraction of the tubercle bacillus, as manifested by a characteristic reaction when tuberculin or purified protein derivative is administered intracutaneously. The red cell sedimentation rate is increased. The symptoms when present are of slight duration and usually the individual is not seen by a physician. In the occasional person for whom a physician is consulted, the symptoms are often mistaken for a mild attack of influenza.

Thus the first manifestations of the disease are usually extremely mild and are unlike those often seen in such other contagious diseases as typhoid and scarlet fever.

With the latter group of diseases, following the first attack the infecting organisms usually die and the body is left with a reasonably good immunity against subsequent attacks. With tuberculosis, however, like syphilis, at the end of the first manifestations the organisms do not die but remain alive and virulent at some of their points of focalization, particularly in the regional lymph nodes. Moreover, the first attack of tuberculosis does not produce dependable immunity against either exogenous or endogenous reinfections.

The organisms in the lesions of the primary complex may remain there and never cause clinical lesions; again, they may spread from place to place through the lymphatic system, the blood stream and the bronchial tubes; they may gain access to the meninges through the rupture of a primary focus in the central nervous system and thus, at any time after the original infection occurs and the primary complex is established, new lesions may appear. If these lesions occur or develop in organs that have communications with the outside world, such as the intestinal, the urinary or the respiratory tract, tubercle bacilli are eliminated, after which they may gain entrance to the bodies of other persons, where they set up foci of disease. Probably the most common site, and certainly the most dangerous one from the standpoint of perpetuation of the disease, is the lung, since involvement of this organ often results in necrosis of sizable areas which find their way into the bronchial tree and are expectorated. Following this evacuation of the dead tissue, cavities remain, in and around which there may be marked proliferation of tubercle bacilli. Because of the communication with the outside world, many of these organisms are eliminated from the body daily. Thus the person who has such a condition has contagious tuberculosis; he may be ill or he may have no impairment whatever of working capacity. Yet wherever he goes and whenever he comes in contact with human beings or animals he may leave a trail of tuberculosis.

In the past, too many physicians have been satisfied to diagnose and treat tuberculosis only after it had reached the consumptive stage. Witness the sanatorium population of this country with from 80 to 90 per cent of patients in the consumptive stage on admission; witness the great volume of literature on treatment dealing largely with drastic procedures, such as extra-pleural thoracoplasty; then remember that all these patients at one time had only microscopic lesions, which could be detected solely by the tuberculin test.

Occasionally one hears the statement that the x-ray inspection of the chest is the best method of case finding in tuberculosis; whether one agrees with this statement will depend on one's interpretation of a case of tuberculosis. He who is satisfied to find tuberculosis only when it is entering on or is already in the consumptive stage will be satisfied with this statement, realizing of course the limitations of the x-ray inspection with reference to the small part of the body viewed in this manner and with man's inability to determine etiology from shadows. But he who appreciates the fact that tuberculosis begins in a microscopic way, when it can be detected only by the tuberculin test, and is cognizant of the fact that, even though the lesions are microscopic the individual has tuberculosis, will never be satisfied with anything less delicate than the tuberculin test in the finding of cases of tuberculosis.

It was not until a specific test for tuberculosis in its very beginning became available that man was able to

study truly its epidemiology. When Colonel Bushnell wrote a monograph on the Epidemiology of Tuberculosis twenty years ago he said "The role of the von Pirquet test in the epidemiology of tuberculosis is destined, it is believed, to become of increasing importance. Especial attention has therefore been paid to it in the hope that the Anglo-Saxon may be inspired by the example of the French and of the Germans to make use of it on a large scale—not only in the tropics, but also at home."

THE TUBERCULIN TEST

With our present methods of examination, and particularly with the tuberculin test, the trail which the contagious tuberculous person leaves can be picked up almost as the hound senses the trail of the fox or as the game animal is trailed in the snow.

The tuberculin test is our most valuable epidemiologic agent. When a good quality of tuberculin or purified protein derivative is carefully administered in the proper dosage by the intracutaneous method, it is almost uncanny with what accuracy it determines the presence of tubercle bacilli in the human or animal body. Even while the lesions are microscopic in size, the tuberculin test betrays their presence. Indeed, tubercle bacilli cannot escape detection by this test more than from three to seven weeks after they are lodged in the tissues of the human body. Thus the trail of tuberculosis may be picked up by the tuberculin test while it is fresh or at almost any subsequent time. In most parts of this country, reasonably fresh trails may be discovered through the examination of children in the preschool or school age. It is unusual for a child of any age to be in association with an adult who has contagious tuberculosis without becoming infected and reacting to tuberculin.

When the trail is detected the next step is to follow the child to the home and there administer the tuberculin test to every member of the household. The test is so specific that it rarely misses the patient with clinical tuberculosis except when the disease is so extensive and the patient so near death that the tissues are becoming desensitized through the large amount of tuberculo-protein being manufactured in the body. Usually in such persons the disease is readily detected by other means. All adult reactors in the household should have x-ray film inspections of their chests. Such an inspection with a single film enables one to visualize reasonably well about 75 per cent of the lung. If lesions are present which have become macroscopic and are located in that part of the lung visualized, they will usually cast shadows on the x-ray film. However, these are only shadows and several diseases cast shadows which cannot be differentiated one from the other; therefore the x-ray film inspection is only a screening process; that is, it selects those members of the household who have disease in the lungs which may be tuberculous.

If one or more members are found to have such shadows, the sputum should be studied immediately for acid-fast bacilli. The presence of such bacilli does not constitute a diagnosis; there are several organisms which morphologically cannot be differentiated from the tubercle bacillus. Their staining qualities are identical. Before they were discovered or well understood, laboratorians made diagnoses of tuberculosis on finding acid-fast bacilli in such material as sputum, gastric contents and urine. This is no longer done by the well informed laboratory worker nor does the physician take the laboratory report indicating the pres-

ence of acid-fast bacilli without further study. When these are present their pathogenicity must be determined. This is best done by guinea pig inoculation. The old procedure of introducing suspected material into the body of the guinea pig and waiting six weeks for developments is obsolete. Too much time is consumed, during which the person who actually has tuberculosis may spread tubercle bacilli to his associates. A method that requires only two weeks or slightly more consists in inoculating animals which do not react to tuberculin. If pathogenic organisms are in the material inoculated, the animal will react to the tuberculin test in about two weeks.

Another method consists in injecting guinea pigs intracutaneously with suspected material. Within seven to twenty-one days a nodule appears at the site of the injection, from which smears may be made and examined for the presence of acid-fast bacilli. As soon as the inguinal lymph nodes have enlarged on the side of the inoculation, the animal may be killed and the node studied for tubercle bacilli to confirm the earlier observation. Woolsey has found that the average time for a diagnosis in this manner is twenty days.

Pickoff injects silica suspension subcutaneously in the flank of the guinea pig and immediately he injects into the same area material suspected of containing tubercle bacilli. The presence of silica apparently stimulates the proliferation of tubercle bacilli and they multiply so rapidly that in some cases within ten to fifteen days material aspirated from this area contains tubercle bacilli in abundance.

Thus, within a brief period after we pick up the trail through the tuberculin reaction of a child we have found the source and have determined the pathogenicity of the organism. This, however, has not been done by slipshod single test methods. It would be most gratifying if any single phase of the examination, such as the x-ray film, would enable us to determine etiology quickly. With the present state of affairs, however, we are rarely able to establish diagnoses on the basis of one phase of the examination. Abrams at one time enjoyed an excellent reputation as an internist but he set himself up as a dictator in diagnosis from a single sample of blood only to fail, as all others must fail who make diagnoses without sufficient evidence.

Failing to find a contagious case of tuberculosis in the immediate household, including the parents, servants and all others who reside there, one should next look to the close relatives, such as the grandparents, aunts and uncles, who frequently are in contact with the child. Since tuberculosis in contagious form often exists in elderly persons, the examination of grandparents may uncover the unsuspected source of infection in the child. In a number of surveys from 1 to 2 per cent of school teachers have been found to have clinical pulmonary tuberculosis. Therefore if the source of the child's infection is not located elsewhere his teachers and other members of the school personnel with whom he has been in contact should be examined. Failing here, the neighbors and close friends of the family may be considered. In following the trail, one may learn that a close associate of the child has died of tuberculosis. With this information the search should not cease, for there may be other cases among the living associates.

Some children become infected with tubercle bacilli through casual contact. Under proper conditions only a minute is required for infection from a contagious case of tuberculosis. Thus at a public meeting place, in a public conveyance, during a brief visit to or from

a distant relative, infection may occur. One picks up the trail through the tuberculin test but it is impossible to follow it. This may be likened to trailing the game bird in the snow or the sand to the point where it takes flight for tens or hundreds of miles.

Another possibility which must never be overlooked is that tuberculosis may exist among the animal associates of the child. The dog, the cat and even the parrot may be eliminating tubercle bacilli which result in infection of the child. In the past, large numbers of children became reactors to tuberculin from bovine tubercle bacilli and even today much of the primary and even clinical tuberculosis in the people of countries that have not controlled tuberculosis among the cattle is due to the bovine type of tubercle bacillus. Therefore in the epidemiologic study one should never overlook the necessary examination of animals who are in contact with the child or whose products the child consumes.

This epidemiologic procedure is not applicable in places where a high percentage of children are infected, indicating the presence of numerous clinical cases of tuberculosis in the community. The trails, as indicated by the tuberculin test, are so numerous, cross one another so frequently and are so superimposed on one another that they may be likened to the trails in the snow of game animals which are abundant. Here they may actually form paths which cross one another in various ways and it is unusual to find a single trail which one can follow to the animal. Where tuberculosis is so prevalent, the only effective procedure is to examine all the adults to find the contagious cases. When these are isolated or treated, an environment is provided in which only a few of the children of the next generation will react to tuberculin. Then the ideal method of trailing tuberculosis with the tuberculin test can be employed. Fortunately, in the greater part of the United States the disease is not so prevalent but that this method is already an effective procedure.

At the Lymanhurst Health Center we operate epidemiologic clinics both for adults and for children. A few persons register in these clinics with symptoms which have caused tuberculosis to be suspected but for the most part the patients are requested to be examined because (1) an adult associate has been found to have contagious tuberculosis or (2) one or more children in a family have been found to react to tuberculin. The examination of the adults consists first of the administration of the tuberculin test. If there is no reaction to a milligram of tuberculin and there is absence of suggestive symptoms, no further phase of the examination is done. Those who react to tuberculin have x-ray film inspections of their chests immediately and, if shadows are found, other phases of the examination, including the laboratory, clinical and even bronchoscopic studies, are made. The whole thought of the examination of such persons is to screen out those who at the moment have tuberculosis which is approaching or is already in the contagious stage in order that they may be treated or isolated. The tuberculin reactors whose chests are clear on all phases of the examination are reexamined annually, as it is well understood that clinical lesions may make their appearance at any time subsequent to the first examination.

The following citations are actual cases and show how effectively tuberculosis can be trailed by administering the tuberculin test among children:

In February 1930 a school girl aged 8 years was found to react to tuberculin. Both her mother and her father were then found to react to the test and x-ray film inspection revealed

evidence of disease in the lungs of both. Further examination proved that the father's disease was tuberculous but in the minimal stage, while the mother's disease was tuberculous but in the far advanced stage. Tubercle bacilli were present in her sputum. This family was earning its livelihood by making and selling pies from house to house. Both the father and the mother were admitted to a sanatorium. The father died there in two months of coronary occlusion. The mother died in April 1939 of pneumonia and pulmonary tuberculosis. Thus the disease in this family was permitted to perpetuate itself and no attempts had been made to stop it until it was found in a school child by the tuberculin test.

A boy aged 12 years was found to react to tuberculin in 1931. The family refused examination until 1934, when the father was found to have advanced pulmonary tuberculosis with tubercle bacilli in the sputum. He was immediately admitted to a sanatorium in April 1934 and died there in December of the same year. A sister was also found to have minimal pulmonary tuberculosis in 1934 and was admitted to a sanatorium. She was discharged in 1937 but was readmitted in 1939 with far advanced disease. One brother and two sisters of this boy and the mother were examined in 1934, all of whom were found to have the first infection type of tuberculosis. Another brother had only an x-ray inspection of his chest, which revealed no evidence of disease. Unfortunately the tuberculin test was not administered and therefore we do not know whether he had the first infection type of tuberculosis.

This family emphasizes the importance of making a provision whereby the private physician and the health officer can promptly follow the trail of tuberculosis rather than have to resort to persuasion, which may require months and even years and may never be successful. The health officer must be permitted to seek out the contagious foci of tubercle bacilli regardless of whose body is concealing them. These foci may be likened to dangerous criminals, for they kill by an insidious method just as surely as the criminals kill by an immediate method. As long as the Federal Bureau of Investigation could not follow certain criminals into any part of the United States but must give up pursuit at state lines, it was difficult to apprehend them. Now that the pursuit can be carried into any part of the nation, the criminal rarely escapes. It even became necessary to prosecute those who concealed criminals knowingly or unknowingly. In some cases this may become necessary for those who conceal contagious tuberculous lesions after educational measures have failed. Indeed, already measures are being provided and enforced to compel the incorrigible person with contagious tuberculosis to be isolated as long as the disease is contagious. In some places special buildings are being contemplated for such persons, where they can be kept under lock and key. This is absolutely essential for every state where incorrigible tuberculous persons exist.

We did not hesitate to isolate "Typhoid Mary" for the last twenty-three years of her life because she left a trail of typhoid wherever she associated with other persons. From the standpoint of contagion, tuberculosis does not differ from typhoid.

We have traced the disease to grandparents and other relatives, to domestics, to teachers and to neighbors of children who reacted to the tuberculin test. In fact, in one group of twenty-five who had only the first infection type of tuberculosis a total of fifty-six contacts were examined, among whom thirty-two were found to have the reinfection type of tuberculosis and the remaining twenty-four had the first infection type of the disease.

In recent years tuberculin has been used extensively to test students on admission to schools of nursing and

medicine. The trail may be followed to the source of some of the reactors. Those who do not react have the test repeated periodically as long as they are non-reactors. While in school, many become reactors; when one takes up this trail, as pioneers in the field, as particularly Diehl and Boynton have done, it usually leads to a tuberculous patient whom the student has examined, nursed or treated. Thus a potent source of infection among hospital personnel was trailed down by the tuberculin test and a great international movement is under way to overcome it.

There is nothing in the entire field of epidemiologic medicine more fascinating than picking up the trail of tuberculosis by the tuberculin test and following to its headquarters in the body of a man or woman. As the criminal leaves traces which lead to his identity and capture, so does tuberculosis leave traces which lead to its discovery. Here one makes a capture of inestimable value to the victim and his associates. In cities and states where tuberculosis is no longer universal among the citizens, all tuberculin reactors (particularly children and young adults) should be reported by physicians to the health department. The modern health officer is interested in epidemiology and because of the nature of his position and trained personnel at his disposal he can take up the trail with the private physician more gracefully and effectively than anyone else in the community.

OTHER METHODS

Since the ideal epidemiologic procedure as described has recently been developed, it has not been in use sufficiently long to bear its best fruit in large volume. Therefore we are compelled still to use old methods which are far less satisfactory but yet are of great value. One of these methods consists in beginning with the infant who has mild or severe manifestations of disease which are called to the attention of the physician before the tuberculin test is administered but complete examination proves that tuberculosis is present. For example:

An infant aged approximately 13 months was found to have the first infection type of tuberculosis in the pneumonic stage. The symptoms were mild but sufficient to call a physician. This child had few adult contacts. The mother and father were found to react to tuberculin but no clinical lesions could be located. One uncle, who had been in contact with the child, reacted to tuberculin but no clinical lesions were detected. A grandmother with whom the infant had lived for a short time and who had fondled him on many occasions resisted the idea of examination because she considered it impossible for any one over 40 years of age to have tuberculosis. However, she had been known to complain of fatigue, dyspnea, anorexia and loss of weight. In about one month after the infant's condition was detected, the grandmother permitted the administration of a tuberculin test, which resulted in a reaction. Following this she made numerous excuses and the x-ray inspection of her chest was delayed for approximately two months. This revealed evidence of disease but another month was lost before she could "remember" to collect a specimen of sputum for examination. This was found to be teeming with pathogenic acid-fast bacilli.

An infant aged 6 months with serious illness was admitted to one of our hospitals in April 1934. His disease proved to be generalized miliary tuberculosis, which was fatal in a short time. Examination of the adult contacts disclosed that the mother had tuberculous lesions in the left lung, and tubercle bacilli were recovered from her sputum.

On June 16, 1935, an apparently healthy infant was born in a small hospital. The nurse in charge of the obstetric and pediatric service gave him the necessary care the first two days of life. He remained in good health until he was 6 weeks old, when he began to cough and had fever. At the age of 8 weeks he died of generalized miliary tuberculosis. An examination of all his adult contacts revealed no case of clinical

tuberculosis except the nurse who cared for him for only two days. She was found to have extensive disease with an abundance of pathogenic acid-fast bacilli in her sputum. The case was tried in the courts and the hospital was required to pay \$1,500 to the family of the infant. The verdict of the jury was upheld by the state supreme court.

Usually the child with tuberculous meningitis or generalized miliary disease is not contagious; therefore it is purely a matter of seeking the source in order to isolate or treat so as to prevent others from becoming infected.

Another epidemiologic procedure consists in beginning with adults who are found to have contagious tuberculosis. Such persons may be found because of (1) declining general health, (2) recent sudden developments such as excruciating pain in the chest or hemorrhage, (3) suspicion of the disease by neighbors or relatives, (4) detection of lesions previously unsuspected during a survey, (5) lesions discovered accidentally while examination is being made for other reasons, such as subsequent to an accident or for life insurance.

This procedure really amounts to back trailing; that is, we examine the persons with whom the recently discovered patient has been in contact and where cultures of tubercle bacilli may have been established. Here one finds the disease in various stages of its development, depending somewhat on the interval of time that has elapsed since the contact which each person had with the patient. The majority of definite contacts will be found to have the first infection type of tuberculosis, as manifested by the tuberculin test. On first examination a few of the adult reactors, perhaps 1 per cent or less, will have evidence of clinical lesions in their lungs or elsewhere; some may already have the disease in the contagious stage. They may or may not have had any significant symptoms. The remainder of the tuberculin reactors will have no evidence of clinical disease that can be detected in the living body by any phase of the examination. Nevertheless each of them has potential clinical tuberculosis and therefore should be adequately examined at least once a year. Among them there may occasionally appear such acute conditions as tuberculous meningitis, generalized miliary disease, tuberculous pneumonia and pleurisy with effusion. These may develop almost over night and the physician can never foresee their coming nor is there anything he can do to prevent them. They constitute a situation that at present is inevitable and unavoidable among persons infected with tubercle bacilli. The more usual development, however, is the chronic form of tuberculosis, which may appear in one or more parts of the body. We watch for it in the lungs not only because we have better methods of examining them than other internal organs but also because it is so likely to become contagious. It rarely occurs during the period of childhood; therefore our observations among reactors can be limited almost entirely to adults. The fact that there is no evidence of clinical disease revealed in the chest of tuberculin reactors today is no guaranty that it will not be present at any subsequent time. Indeed, there is no time limit; that is, one cannot say that after a period of five years there is no need for further examinations of tuberculin reactors; they must be continued as long as the individual reacts to tuberculin.

On Jan. 23, 1934, a girl aged 19 years reported to her physician because of illness. He found evidence of advanced pulmonary tuberculosis in the left lung, which was in the contagious stage. In back trailing, the tuberculin test revealed the presence of the first infection type of tuberculosis in the

bodies of each of her three sisters. The x-ray films of the chests of two of the sisters aged 17 and 18 years revealed no evidence of disease. However, one year later each of them had unmistakable pulmonary tuberculosis of the reinfection type, which was detected in the presymptom and the precontagious stage.
